Abstract

Analysis of passive microwave brightness temperatures from the space-borne Special Sensor Microwave Imager (SSM/I) documents a record surface snowmelt over high elevations (above 2000 m) of the Greenland ice sheet during summer of 2007. To interpret this record, results from the SSM/I are examined in conjunction with fields from the National Centers for Environmental Prediction/National Center for Atmospheric Research reanalysis and output from a regional climate model. The record surface melt reflects unusually warm conditions, seen in positive summertime anomalies of surface air temperatures, downwelling longwave radiation, 1000–500 hPa atmospheric thickness, and the net surface energy flux, linked in turn to southerly airflow over the ice sheet. Low snow accumulation may have contributed to the record through promoting anomalously low surface albedo.

1 Introduction

The most visible evidence of Arctic environmental change is its rapidly shrinking sea ice cover. Based on analysis of time series that combine records from the space-borne Scanning Multichannel Microwave Radiometer (SMMR, 1979–1987) and the Special Sensor Microwave/Imager (SSM/I, 1988–2007) negative trends in Northern Hemisphere sea ice extent encompass all months (Serreze et al., 2007). The summer and autumn of 2007 serve as exclamation points on these trends, with ice extent falling to new record lows (Comiso et al., 2008; Stroeve et al., 2008). Interestingly, this remarkable event was attended by record summer surface snowmelt over the Greenland ice sheet, also punctuating a general trend. This is seen in the analyses of both Tedesco (2007a) and Mote (2007). The record identified in the former study is based on an annual surface melting index (MI, the product of melt area and the number of melting days) for the part of the ice sheet above 2000 m, based on SSM/I data. The latter study focuses on a functionally similar index computed for the entire ice sheet,

Interactive Discussion

assessed from a time series combining records from SSM/I, SMMR and the Electrically Scanning Microwave Radiometer (ESMR, 1973, 1974 and 1976). The present paper addresses the causes of the record 2007 surface melt.

Variations in the extent and duration of summer melt over Greenland reflect a suite of processes intimately tied to air temperature and the surface energy balance. Horizontal atmospheric heat transports are important through impacts on the longwave radiation to the surface and vertical turbulent heat fluxes. Cloud cover reduces shortwave radiation to the surface, but tends to increase the downwelling longwave component. Surface albedo is key, through both influencing solar radiation absorbed by the surface and by modulating cloud radiative forcing. Albedo can be highly variable, and tends to decrease through the melt season as snow grain sizes increase as a consequence of constructive metamorphism.

We evaluate mechanisms contributing to the record surface melt identified by Tedesco (2007a) through analysis of surface air temperature and circulation fields from the National Centers for Environmental Research (NCEP/NCAR) reanalysis (Kalnay et al., 1996) in conjunction with anomalies in components of the surface energy balance depicted by the regional climate model MAR (for Modèle Atmosphérique Régional) (Fettweis, 2007). We focus first on the ice sheet as a whole and then turn attention to its southwest portion, where surface melt anomalies reached their largest positive values.

2 Surface melting for summer 2007

The microwave brightness temperature over dry snow is relatively low compared to when snow is wet. When snow melts, liquid meltwater forms in the snow pack and an increase in the emitted microwave radiation occurs (Ulaby and Stiles, 1980), mainly as a consequence of the increased imaginary part of snow permittivity which, in turn, also leads to an increase in the absorption. Changes in melt duration and extent over Greenland have been examined via various techniques using passive microwave data,

Interactive Discussion

including the seasonal change in emissivity (Mote and Anderson, 1995; Mote, 2007), the frequency dependence of emissivity (Abdalati and Steffen, 1997; Steffen et al., 2004) and the diurnal change in brightness temperature using ascending and descending orbital passes (Tedesco, 2007a,b).

5 Tedesco (2007a) made use of SSM/I brightness temperatures at 19.35 GHz, horizontal polarization, available at 25 km resolution from the National Snow and Ice Data Center (Armstrong et al., 1994). Building on Tedesco (2007a), panels a and b of Fig. 1 show, respectively, the spatial distribution of melting day anomalies in 2007 (number of melting days in 2007 at each grid cell minus the average for the period 1988–2006) and time series of the annual MI for the ice sheet as a whole (gray bars) and for regions above 2000 m (black bars). To obtain the annual MI, the number of melting days for each pixel is first multiplied by the pixel area ($\sim 625 \text{ km}^2$). These values are then summed for all pixels experiencing melt. Panels c and d show the 2007 melt extent (areas where melting occurred for at least one day) and its time series.

15 For the ice sheet as a whole, the annual MI for 2007 was 30% above average but still well below peak values estimated for 1998 and 2002. However, the MI above 2000 m set a new record of $4\,008\,750 \text{ km}^2 \times \text{days}$, beating the previous high of $3\,486\,875 \text{ km}^2 \times \text{days}$ set in 1999. From Fig. 1a, it is apparent that some areas in the southwest part of the ice sheet experienced melting up to 25–30 days longer than average (redder colors). Updated through 2007, the linear trend in the MI above 2000 m stands at $126\,487 \text{ km}^2 \times \text{days/yr}$. Note further that 2007 does not stand out in terms of the melt area, either for the ice sheet as a whole or regions above 2000 m (Fig. 1c,d). Hence the key feature of 2007 in this analysis is the extreme high melting index at the higher ice sheet elevations.

25 Mote (2007) presents a map similar to Fig. 1a, but with melting day anomalies for 2007 calculated with respect to the longer record (1973–2007) that includes SMMR and ESMR. The major difference compared to Fig. 1a is that the area with strong positive departures over southwestern Greenland extends further east. Peak departures are also larger, locally exceeding 50 days with melting. This reflects differences in

Extreme surface melt over southwestern Greenland in 2007M. Tedesco et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

both the baseline period for computing anomalies and analysis techniques (notably an emission model using scattering coefficients that are empirically derived from brightness temperatures before the onset of melt each year, see [Mote and Anderson \(1995\)](#) for details).

5 Instead of a MI (Fig. 1b) [Mote \(2007\)](#) provides time series of seasonal melt departures (SMD) assessed for the entire ice sheet, in which daily departures in melt extent, calculated with respect to 1973–2007 means, are summed through each melt season. While functionally similar to the MI of [Tedesco \(2007a\)](#), the SMD approach is designed to mitigate the effects of missing days in the satellite records, most problematic for
10 SMMR and ESMR. From the SMD time series, the record melt of 2007 stands out more prominently than shown in Fig. 1b, with 1998 representing the previous record.

3 Addressing the causes of the record melt

Panels a and b of Fig. 2 show the spatial pattern of 2 m (hereafter surface air) temperature anomalies (K) from the NCEP/NCAR reanalysis and as simulated by the MAR, averaged for summer (June through August, JJA) 2007. Anomalies are calculated with
15 respect to 1988–2006 JJA averages. The surface air temperature in the NCEP/NCAR reanalysis represents interpolation between the lowest model analysis level and the modeled surface skin temperature. MAR ([Gallée and Schayes, 1994](#)) is coupled to the 1-D Soil Ice Snow Vegetation Atmosphere Transfer (SISVAT) scheme ([De Ridder and Gallée, 1998](#)). [Fettweis \(2007\)](#) examined a 28-year surface mass balance simulation
20 (1979–2006) over the ice sheet with the MAR at a horizontal resolution of 25 km. For the present paper, we extended this simulation to the end of 2007. Data from the European Centre for Medium Range Weather Forecasts (ECMWF, <http://www.ecmwf.int/>) ERA-40 reanalysis (1977–2002) and ECMWF operational analyses (2002–2007) were
25 used to initialize meteorological fields at the beginning of the simulation and to force the lateral boundaries every six hours during the simulation.

Both NCEP/NCAR and the MAR indicate that surface air temperature was above the

average over most of the ice sheet. While general agreement is not surprising given that the NCEP/NCAR and ECMWF systems assimilate the same basic data streams, in contrast to NCEP/NCAR, the largest anomalies from MAR (exceeding 4°C) coincide closely to the region of peak melting day anomalies seen in Fig. 1a. This may reflect the higher resolution of MAR compared to the NCEP/NCAR fields, its more robust treatment of the surface energy balance, as well as differences in the depiction of regional circulation between NCEP/NCAR and the operational ECMWF fields used as boundary forcing for MAR.

Figure 2c–e shows corresponding anomalies of incoming longwave and shortwave radiation at the surface (W m^{-2}), and surface albedo (%), as simulated from MAR. Incoming longwave radiation anomalies (W m^{-2}) are positive over most of the ice sheet, largest on the western side where they reach $+22 \text{W m}^{-2}$. Air temperature, cloud properties and humidity may all be contributing to these anomalies. Consistent with positive anomalies in simulated cloud optical thickness (not shown), anomalies of incoming shortwave radiation (d) are generally negative, again most prominent over the western side of the ice sheet. Finally, it is clear that surface albedo (e) was below average almost everywhere, but especially along the coast (down to -30%).

The positive anomalies in surface air temperature and downwelling longwave radiation simulated with the MAR are consistent with the melt pattern shown in Fig. 1a. Although anomalies in shortwave radiation were slightly negative, the MAR results point to a countering effect by reduced surface albedo. To help further understand the record melt event from the viewpoint of the surface energy budget, the remaining panels in Fig. 2 show MAR-based anomaly maps of the fluxes of latent heat (f), sensible heat (g), net longwave radiation (h), net shortwave radiation (i) and the net surface energy flux (j), the latter representing the sum of the radiation terms and the two turbulent heat fluxes (sensible and latent). Positive anomalies mean more energy to the surface.

Anomalies of the latent heat flux are generally small. Those of sensible heat are negative (lower than -20W m^{-2}) along the west coast of the ice sheet, positive along the

east coast, and generally small over the interior section except for the west-central portion, where positive values of $5\text{--}10\text{ W m}^{-2}$ are found. Pointing to the dominant effects of reductions in surface albedo over cloud cover, anomalies in net shortwave radiation are strongly positive along the coast (more than 20 W m^{-2}). Despite negative anomalies in the downwelling shortwave flux, positive anomalies in net shortwave ($5\text{--}15\text{ W m}^{-2}$) also dominate most of the ice sheet except for the highest elevations. Anomalies in net longwave radiation to the surface are strongly positive over the southwest part of the ice sheet.

The overall result is strong positive anomalies in the net surface energy flux over the western part of the ice sheet, consistent with the location of large melting anomalies (Fig. 1a). These positive net surface energy flux anomalies are in turn driven by the combined effects of positive anomalies in net longwave radiation, sensible heat and net shortwave radiation, the latter linked to negative albedo anomalies. While the albedo anomalies are themselves consistent with the effects of strong melt on increasing snow grain size, their presence in the MAR outputs may also be a consequence of low simulated snow accumulation over the winter of 2006–2007 (Fettweis, 2007). As melt progressed, it may have exposed bare ice (in the lower elevations) and old snow sooner than in previous years (such processes are treated in the MAR framework).

It is useful to focus further on the region over southwestern Greenland where the most extreme positive melting anomalies occurred. This region ($64.5\text{--}67^\circ\text{ N}$, $50\text{--}47.5^\circ\text{ W}$), where the melt duration was 25–30 days above average, is bounded by the square shown in Fig. 1a. It coincides closely to the area of peak melting day anomalies shown by Mote (2007).

For this analysis, we assess daily values and anomalies of the MI ($\text{km}^2 \times \text{days}$) from SSM/I, NCEP/NCAR estimates of surface air temperature (K) and 1000–500 hPa thickness (m). These are complemented by time series from the MAR of downwelling longwave and shortwave radiation (W m^{-2}), albedo (%), and the net surface energy flux (W m^{-2}). Time series from SSM/I and NCEP/NCAR averaged over the study region are plotted in Fig. 3 for 1 June through 31 August. As before, anomalies are with respect to

Interactive Discussion

1988–2006. The 1000–500 hPa thickness is proportional to the mean temperature of that pressure layer, providing information on tropospheric warmth to complement the surface air temperature estimates.

The MI, surface air temperature and thickness anomalies (Fig. 3a–c) are persistently positive through the summer period, with strong imprints of variability at synoptic timescales. Anomalies in cloud fraction derived from the Moderate Resolution Spectroradiometer (MODIS), not shown here, document high variability in both magnitude and sign. MODIS cloud fraction anomalies are referenced to 2000–2006 as the record starts in 2000. Results from MAR show a mix of positive and negative anomalies in the shortwave radiation flux incident to the surface (Fig. 4a), but with strong negative values early in the record. Averaged for the summer, and qualitatively consistent with the MODIS results suggesting that cloud fraction over this period was slightly (3%) greater than normal, the shortwave flux was slightly (4 W m^{-2}) below the mean. Anomalies in simulated albedo (Fig. 4b) are persistently negative. As expected, modeled anomalies in the incident longwave radiation are persistently positive (Fig. 4c). The net surface energy flux anomaly is in turn persistently positive (Fig. 4d). Note the two periods with strongly negative albedo anomalies centered about 11 July and 12 August. While it might be expected that these would correspond to periods when the simulated net surface heat flux was strongly above average, no relationship is apparent.

4 Conclusions

We conclude that the record Greenland surface melt in summer 2007 identified by Tedesco (2007a) and Mote (2007) is a reflection of unusually warm conditions, seen in anomalies of surface air temperature, 1000–500 hPa atmospheric thickness and modeled fields of downwelling longwave radiation and the surface sensible heat flux. These effects, along with reduced surface albedo, are manifested in consistently positive anomalies in the modeled net surface heat flux through the summer season. The 2007 melting index was 2.1 standard deviations (Z-scores) above the mean. However,

Interactive Discussion

given the short record available from SSM/I and SMMR, the question of whether this melt event is outside of the envelope of natural variability cannot be readily addressed.

As introduced earlier, the record surface melt over Greenland in 2007 was attended by a record low in summer Arctic sea ice extent. The latter represents response to a thinning ice pack in recent years coupled with an unusual atmospheric pattern in summer 2007, featuring high pressure over the central Arctic Ocean and low pressure over central and western Siberia. Resultant southerly winds promoted high temperatures north of Siberia and transport of ice away from the Siberian coast (Stroeve et al., 2008). While the NCEP/NCAR data also document southerly airflow over the southeastern part of the Greenland ice sheet, consistent with the region of strongest melt, this regional pattern shows no obvious link to the pattern associated with the sea ice loss. The common factor was that both the sea ice cover and Greenland were under the influence of warm conditions. Indeed, warm conditions were pervasive over northern high latitudes, contributing strongly to the global-averaged temperature in 2007 being the second highest of the instrumental record according to the Goddard Institute for Space Sciences analysis (<http://data.giss.nasa.gov/gistemp/2007/>).

While melting at high elevations is not contributing to this process, it leads to a reduction in ice sheet albedo. Interestingly, the 2007 surface mass balance over the ice sheet of $-65 \text{ km}^3/\text{yr}$ as simulated by the MAR is the most negative of the period 1979–2007 (Fettweis, 2007). While strong melt contributed to this negative mass balance anomaly, the larger contribution came from anomalously low snowfall ($508 \text{ km}^3/\text{yr}$ water equivalent). Mote (2007) noted that while the seasonal melt departure index is significantly correlated with summer temperatures at coastal stations around Greenland, 2007 showed more melt than expected based on these records. The MAR simulation lends credence to his suggestion for a role of reduced albedo.
