Abstract

Spatial and temporal characteristics of the Storfjorden polynya, which forms regularly in the proximity of the islands Spitsbergen, Barentsøya and Edgeøya in the Svalbard archipelago under the influence of strong north-easterly winds, have been investigated for the period 2002/2003 to 2013/2014 using thermal infrared satellite imagery. Thin-ice thicknesses were calculated from MODIS ice-surface temperatures, combined with ECMWF ERA-Interim atmospheric reanalysis data in an energy-balance model. Based on calculated thin-ice thicknesses, associated quantities like polynya area and total ice production were derived and compared to previous remote sensing and modeling studies. A basic coverage-correction scheme was applied to account for cloud-gaps in the daily composites. The sea ice in the Storfjorden area experiences a late fall freeze-up in several years over the 12 winter-period, with an increasing frequency of large polynya events until the end of December. During the regarded period, the mean polynya area is $4555.7 \pm 1542.9 \text{km}^2$. The average ice production in the fjord is estimated with $28.3 \pm 8.5 \text{km}^3$ per winter and therefore lower than in previous studies. Despite this comparatively short record of 12 winter-seasons, a significant positive trend of $20.2 \text{km}^3$ per decade could be detected, which contrasts earlier reports of a slightly negative trend in accumulated ice production prior to 2002. Derived estimates underline the importance of this relatively small coastal polynya system considering its contribution to the cold halocline layer through salt release during ice formation processes.

1 Introduction

Recurrent polynyas are considered to play an important role for sea ice production and ocean circulation (Barber and Massom, 2007). The knowledge of ice production in the Arctic is of vital interest for the understanding of the Arctic climate system and the verification of climate and ocean models. Divergent ice motions due to wind are the main cause for the opening of near-coastal polynyas (Smith et al., 1990). During winter, these
areas of open water or thin ice, exposed to the cold atmosphere, are characterized by strong ice production and brine release and modify the atmospheric boundary layer (Ebner et al., 2011; Bauer et al., 2013). The timing, duration and size of a polynya can often have large interannual variations because of the general interannual variability of atmosphere-ice-ocean interaction processes (Morales-Maqueda et al., 2004). A precise derivation of the thin-ice thickness (TIT) distribution, the areal extent of a polynya (here defined as open water and thin-ice below 0.2 m) and the amount of local sea ice production is therefore an important step towards a comprehensive understanding of physical processes in the Arctic shelf regions and the Arctic sea ice cover in general. Ice production in thin-ice regions can either be estimated by the use of remote sensing methods (Willmes et al., 2010), or by using model approaches. The use of thermal infrared and microwave remote sensing data offers the opportunity for daily monitoring of thin-ice thicknesses and their distribution on large spatial scales (Yu and Rothrock, 1996; Willmes et al., 2010; Adams et al., 2013).

Storfjorden (see Fig. 1), situated in the southeastern part of the Svalbard archipelago between the main island of Spitsbergen in the west and Barentsøya/Edgeøya in the east, is a region of high coastal polynya activity during winter, as reported by a number of earlier studies (e.g. Haarpaintner et al., 2001; Skogseth et al., 2004). Two shallow straits, Heleysundet and Freemansundet, connect the northern part of Storfjorden with the Barents Sea and show tidally induced currents as well as exchange processes between water masses inside the fjord and the Barents Sea (Skogseth et al., 2013). Persistent and strong northerly to north-easterly winds are the main cause for larger polynya openings inside Storfjorden. These opening events may result in large volumes of brine-enriched shelf water, which can be significant regarding the total amount of bottom water in the Arctic (Skogseth et al., 2004; Hendricks et al., 2011). Besides thermodynamically induced ice growth in Storfjorden during wintertime, the dynamical part due to rafting and deformation processes may play a substantial role in the overall ice thickness distribution, as southerly (onshore) winds can potentially advect sea ice from the Barents Sea into the fjord (Hendricks et al., 2011). An estimation of
thermodynamic ice production (IP) within the open water and thin-ice area (i.e. Storfjorden polynya) has been conducted in previous studies using mainly microwave remote sensing (both passive and active systems) in combination with different model approaches. Therein, values are ranging between 20 and 35–45 km$^3$ for single winter-seasons (November–May) between 1997/1998–2000/2001 (Haarpaintner et al., 2001; Skogseth et al., 2004, 2005) and 47 km$^3$ when averaged over the winter-seasons (October/November–June/July) from 2002/2003–2011/2012 (Jardon et al., 2014).

Based on daily empirically derived ice thickness distributions in thin-ice areas at a comparatively high spatial resolution, we perform a broad investigation on the associated quantities polynya area and ice-production for the period between 2002/2003 and 2013/2014 using high-resolution Moderate Resolution Imaging Spectroradiometer (MODIS) thermal infrared data. The presented results will aid to get a more comprehensive understanding of the polynya dynamics in Storfjorden as well as associated processes over both annual and interannual timescales (in the course of this paper, the term “annual” refers to one winter-season from November–March). Further, results will contribute to pan-arctic studies of polynya dynamics.

2 Data and methods

2.1 MODIS ice-surface temperatures

Thin-ice thicknesses are computed using the MOD/MYD29 sea-ice product (Hall et al., 2004; Riggs et al., 2006), derived from MODIS satellite data. We used data from both MODIS instruments onboard Terra and Aqua polar-orbiting satellite platforms. It is available from the National Snow and Ice Data Center (NSIDC) located in Boulder, USA (ftp://n5eil01u.ecs.nsidc.org/SAN/). The product contains swath data of ice-surface temperatures (IST). IST swaths have a spatial resolution of 1 km $\times$ 1 km at nadir. Under ideal conditions (clear sky and low amount of water vapor in the atmosphere), the accuracy is given with $\pm$1.6 K (Hall et al., 2004). An important remark to
the accuracy-assessment conducted by Riggs et al. (2006) is the restriction to daytime pixels only, as no nighttime validation has been done.

For our analysis, swaths covering the Storfjorden area were extracted using metadata information for each MODIS swath, resulting in 27 individual swaths per day on average for later composite generation (nighttime scenes). The total number of incorporated MODIS swaths is illustrated in Table 1. As MODIS swath data presumably suffer from inherent panoramic distortion effects, all IST-swaths were mapped onto a 2 km × 2 km (0.018°) equirectangular grid covering the southern part of Svalbard (75–80° N, 10–30° E).

A polynya mask (red area in Fig. 1) is applied in order to cover an area comparable to previous studies, as well as to limit the probability of remaining hidden cloud artifacts. The mask comprises a total area of 12 594 km² and has its southern limit at 77° N (following Skogseth et al., 2004), where a 120 m deep sill serves as kind of a boundary for the accumulation of brine-enriched shelf water in the Storfjorden basin (see Fig. 1).

2.2 ERA-interim reanalysis

For the calculation of TIT, atmospheric variables from the ERA-Interim reanalysis product (Dee et al., 2011) are used to provide 2 m temperature, 2 m dew point temperature, 10 m wind speed components (u and v) and the mean sea-level pressure at a resolution of 6 h. The data set is provided by the European Center for Medium-Range Weather Forecasts (ECMWF) in a horizontal resolution of 0.75° (~ 79 km). As the satellite data set is by far spatially higher resolved than the atmospheric data set, a linear interpolation of the ERA-Interim data is performed to match the MODIS data. In the course of the TIT-calculations, each MODIS swath is linked to the closest time step of the atmospheric fields.
2.3 Thin-ice thickness retrieval using a 1-D thermodynamic surface energy model

In order to derive daily TIT-distributions, we use an approach that follows the work of Yu and Rothrock (1996), Yu and Lindsay (2003) and Drucker et al. (2003), with most recent improvements and modifications made by Willmes et al. (2010, 2011) and Adams et al. (2013). The applied method utilizes the distinct relationship between ice surface temperature and thickness of thin ice depending on atmospheric energy fluxes. The IST of very thin ice (with no snow cover) is close to the freezing point of the upper ocean layer and decreasing IST can be observed for thicker ice (Drucker et al., 2003; Kwok et al., 2007). However, IST is governed by atmospheric radiation fluxes and turbulent fluxes of heat, which does not allow for a simple relationship between IST and ice thickness. The thin-ice thickness \( h_{\text{ice}} \) is therefore calculated using a 1-D thermodynamic sea ice model.

Several assumptions have to be made to apply this model. First, the temperature profile through the ice is assumed to be linear. This approximation is valid for \( h_{\text{ice}} \leq 0.5 \text{ m} \) (Drucker et al., 2003). Second, the water temperature at the boundary between ice and ocean is constant and at its freezing point \( (T_f = 271.35 \text{ K}) \). Third, the ice is assumed to be free of snow. The ice thickness is calculated by using MODIS IST and ERA-Interim reanalysis data. The method is based on the condition, that the conductive heat flux through the ice \( (Q_{\text{ice}}, \text{Eq. 1}) \) equals the total heat flux to the atmosphere \( (Q_{\text{atm}}, \text{Eq. 2}) \). This implies, that all energy loss at the ice-surface is compensated by the conductive heat flux \( Q_{\text{ice}} \).

\[
Q_{\text{ice}} = \kappa_{\text{ice}} \cdot \frac{(T_{\text{surf}} - T_f)}{h_{\text{ice}}} \quad (1)
\]

\[
Q_{\text{atm}} = Q_0 - H_0 - E_0 \quad (2)
\]

where \( Q_0 \) is the net radiation balance, \( H_0 \) and \( E_0 \) are the turbulent fluxes of sensible heat and latent heat, respectively, \( \kappa_{\text{ice}} \) is the thermal conductivity of sea ice, \( T_{\text{surf}} \) is the
surface temperature, $T_f$ the freezing point of sea water and $h_{\text{ice}}$ is the ice thickness. Because of difficulties with the parametrization of shortwave radiation terms (Adams et al., 2013), only nighttime scenes were incorporated into the calculations (by checking the solar incidence angle on a pixel-by-pixel basis), so that the radiation balance $Q_0$ simplifies to the long wave radiation terms $L \downarrow$ and $L \uparrow$. Upwelling longwave radiation $L \uparrow$ is calculated using the IST from MOD/MYD29 with the surface emissivity $\epsilon_s$ set to 1. $L \downarrow$ can be obtained using ERA-Interim 2 m temperatures and the atmospheric emissivity $\epsilon_{\text{atm}}$, calculated using the formulation of Jin et al. (2006). Turbulent fluxes of sensible ($H_0$) and latent ($E_0$) heat in Eq. (2) are calculated using an iterative bulk approach by Launiainen and Vihma (1990), where near surface stratification is considered using Monin–Obukhov similarity theory and associated universal functions for the heat transfer coefficients $C_H$ and $C_E$. The 10 m wind speed is interpolated to the 2 m level. A constant roughness length for momentum $z_0 = 1 \times 10^{-3}$ m is used. As could be shown by Adams et al. (2013), the standard approach used in previous studies using constant heat transfer coefficients tends to underestimate the ice thickness by approximately 7 cm on average, when compared to an iteratively calculated heat transfer coefficient. To obtain the ice thickness $h_{\text{ice}}$, the total atmospheric flux $Q_{\text{atm}}$ (Eq. 2) is set equal to the conductive heat flux through the ice ($Q_{\text{ice}}$; Eq. 1) and Eq. (1) is solved for the ice thickness $h_{\text{ice}}$.

TIT is calculated using a value for the thermal conductivity of $\kappa_{\text{ice}} = 2.03 \text{W m}^{-2} \text{K}^{-1}$ (Drucker et al., 2003). It is assumed to be uniform at a given pixel location and therefore hypothetical (Tamura and Ohshima, 2011). The described method is only applicable to clear sky conditions, as clouds and fog strongly influence the accuracy of the recorded IST (Riggs et al., 2006). We constrain our analysis to TIT-values $\leq 0.2$ m, as this range is regarded sufficient to get reliable results for ice production (Yu and Rothrock, 1996; Adams et al., 2013).

In a sensitivity analysis of the above described method, Adams et al. (2013) state an uncertainty for the TIT retrieval of $\pm 1.0$, $\pm 2.1$ and $\pm 5.3$ cm for TIT classes 0–5, 5–10 and 10–20 cm, respectively.
2.3.1 Calculation of daily TIT-composites

From all available MODIS swaths covering the Storfjorden polynya region, daily composites of IST and TIT were computed. The TIT is first calculated from each swath on its own with the procedure described in Sect. 2.3. Subsequently, the mean TIT is computed pixel-wise and stored with its corresponding IST value.

By using daily composites, the daily IST-coverage within the polynya mask is significantly increased compared to single swaths, reaching an average value of 82 % for the winter-seasons 2002/2003 to 2013/2014. Figure 2 shows the seasonal and inter-annual variability of IST-coverage. Noteworthy is a very low coverage in November to early January 2009/2010, as well as generally less frequent coverage at the beginning (November) and end (March) of each winter-season. The latter effect originates from the previously stated restriction to nighttime scenes and consequently a reduction in the amount of available MODIS swaths. Hence, it is also the main reason why the months of October and April were left out in our investigations.

2.3.2 Derivation of ice production and polynya area

Following Tamura et al. (2007, 2008) and Willmes et al. (2011), daily ice production rates are calculated from the heat loss at the ice surface by assuming that the entire heat loss to the overlying atmosphere contributes to new ice formation.

$$\frac{\partial h}{\partial t} = \frac{-\bar{\dot{Q}}_{\text{ice}}}{\rho_{\text{ice}} \cdot L_f}$$

Therein, $\frac{\partial h}{\partial t}$ stands for the ice production rate, $\bar{\dot{Q}}_{\text{ice}}$ is the daily mean conductive heat flux through the ice, $\rho_{\text{ice}}$ is the density of sea ice (taken as $\rho_{\text{ice}} = 910 \text{ kg m}^{-3}$) and $L_f$ is the latent heat of fusion of ice ($L_f = 0.334 \text{ MJ kg}^{-1}$; e.g. Tamura and Ohshima, 2011). Note that the negative sign in the right side of Eq. (3) handles the convention that $Q_{\text{atm}}$ is considered positive when the surface gains energy, as well as considering
that ice production only takes place when there is a net energy loss from the surface. Multiplying $\frac{\partial h}{\partial t}$ with the areal extent of each pixel in the regarded region yields the volume ice production rate $\frac{\partial V}{\partial t}$ (IP). Ice production rates are calculated for each pixel with a TIT $\leq 0.2$ m, and afterwards extrapolated to daily rates for later accumulation and/or averaging. Considering the total polynya area (POLA), a threshold of $h_{\text{ice}} \leq 0.2$ m is applied to identify TIT-pixels from the daily composites as part of the POLA. The total area of those pixels is then accumulated to obtain the total daily POLA in km$^2$.

2.3.3 IST-coverage correction

Cloud-induced gaps in our daily TIT and IST composites are a serious problem when we want to compare our initially calculated POLA and IP to estimates from other studies, in which the use of active and passive microwave remote sensing systems largely reduces the effect of atmospheric disturbances.

To overcome these difficulties, a simple scaling approach is applied that works under the assumption, that pixels in the uncovered part of the masked (Fig. 1) daily composites also contribute to the total POLA by approximately the same proportion as those areas that are covered by a IST-signal.

The initially calculated daily POLA is therefore scaled by a factor $F$:

$$F = \frac{1}{\text{coverage}}$$

$$\text{POLA}_{\text{CC}} = \text{POLA} \cdot F.$$  

The coverage in Eq. (4) could range from 0–1, but we apply the correction only for coverages exceeding 0.5. Similarly, estimated ice production (IP) values are also scaled by the same factor yielding a corrected ice production $\text{IP}_{\text{CC}}$.

Application of this correction scheme is limited to cases where the daily IST-coverage (compare Fig. 2) within the fjord (i.e. the predefined polynya mask) surpasses a threshold of 50%. By using this threshold, unrealistically high $\text{POLA}_{\text{CC}}$ and $\text{IP}_{\text{CC}}$ values are avoided. Otherwise, both $\text{POLA}_{\text{CC}}$ and $\text{IP}_{\text{CC}}$ are linearly interpolated using bounding days with a coverage fulfilling this precondition.
3 Results

Figure 3 shows histograms of the mean relative TIT-distributions for ice thicknesses below 0.2 m, based on daily composites for the winters 2002/2003 to 2013/2014. A temporal differentiation between the beginning of the freezing season (November–December) and the end of the freezing season (January–March) as well as a combined distribution for the whole winter period is given. Error-bars refer to ±1 SD of the interannual averaged distribution frequencies. Between November and March, ice thinner than 0.02 m contributes around 15% to the total polynya area in an average winter-season. Due to a higher sensitivity of open water and very thin ice for sea smoke effects and consequently an exclusion of thin-ice pixels by the cloud mask, this thickness class is potentially biased (Willmes et al., 2011). The average ice thickness within the polynya mask is 10 ± 1.8 cm. Thicker ice classes (> 0.1 m) cover around half of the entire Storfjorden polynya in January to March and show overall lower contributions at the beginning of the freezing season. This follows from the high contribution of very thin ice in November to December, where over 60% of the total POLA consists of ice thinner than 0.1 m. SD are highest in the lowest thickness classes (< 0.04 m) and appear to be lower towards the end of the freezing season, possibly indicating a stronger seasonal variability of ice thickness distributions within the polynya in November and December over the twelve year record (also apparent in relative TIT-frequencies for November–December; Fig. 4).

Spatial distributions of the relative TIT-frequency for 2002/2003 to 2013/2014 are presented as a seasonal comparison between the beginning of each freezing season (November–December, Fig. 4) and the end of each freezing season (January–March, Fig. 5). Therein, a pixel-value of e.g. 0.25 means that on 25% of all days, a TIT-threshold of 0.2 m was not exceeded. Following the previously stated definition of a polynya, these pixels represent the number of polynya-occurrences in the given period. Figure 5 shows, that the main regions for polynya development towards the end of the freezing season are at the lee-sides of Barentsøya and Edgeøya at the eastern

At the beginning of the freezing season (Fig. 4), annual distributions show a more variable pattern of TIT-frequencies. In some years (e.g. 2007, 2009, 2012), frequencies exceeding 0.3 cover large areas within the masked area in Storfjorden, which might be an effect of a late fall freeze-up and subsequently longer periods with thin ice and open water in the fjord. In other years (e.g. 2003, 2004), the observed pattern of high TIT-frequencies is similar to typical polynya locations between January and March, indicating an earlier freeze-up of the ice cover in Storfjorden.

Frequent TIT-occurrences in the southern part of Storfjorden could originate from a generally northwards retreating ice edge in Storfjorden in some of the regarded winter-seasons. This becomes most obvious in 2006, 2008 and 2012 to 2014 (Fig. 5). Low values (< 0.05) at the (north-) western side of Storfjorden towards the end of a freezing season (Fig. 5) further indicate typical fast-ice areas, which are most pronounced in the years 2004, 2005, 2007 and 2011.

The daily POLA\textsubscript{CC} for all winters (November–March) between 2002/2003 and 2013/2014 is presented in Fig. 6. Highest POLA\textsubscript{CC} values are generally found in November and December, which might be an effect of the already mentioned late fall freeze-up and therefore very thin newly formed ice (compare Figs. 3a and 4) in large parts of Storfjorden. From 2006 to 2008 and 2012 to 2013, this effect even extends well into January with a series of large POLA\textsubscript{CC} events (> 5000 km\textsuperscript{2}) developing in February and March.

The mean (November to March) POLA for the entire regarded period amounts to 3511.8 ± 999.6 km\textsuperscript{2}, with an increase of 29 % for POLA\textsubscript{CC} when the presented coverage correction is applied. Around 60 % of this area consists of ice thinner than 10 cm. A complete overview on wintertime mean POLA and POLA\textsubscript{CC} values is given in Table 2.

A spatial overview of the resulting accumulated daily ice production rates (in m winter\textsuperscript{-1}), averaged between 2002/2003 and 2013/2014 is presented in Fig. 7. Largest IP occurs in regions which also show high TIT-frequencies (Fig. 5). Average IP
values in the western part of Storfjorden are generally lower, as thin-ice in these areas is mainly present at the beginning of the freezing season.

Maximum daily ice production rates in the fjord can reach as high as 26 cm d\(^{-1}\) (winter-season 2006/2007), with the highest rates occurring on average in the northern part of Storfjorden (north of 77.5° N).

Figure 8 shows values of accumulated ice production per winter-season from November to March, both with and without applied coverage-correction. On average, the correction scheme increases the wintertime ice production by approximately 30%. While average IP-values range between 21.7 ± 5.9 km\(^3\) (no CC) and 28.3 ± 8.5 km\(^3\) (CC), a high interannual variability of ice production is found, with values as low as 16.1 km\(^3\) (CC; no CC –16%) in 2002/2003 and up to 47.2 km\(^3\) (CC; no CC –31%) in 2012/2013. A detailed overview for each winter-season is given in Table 2. Regardless of an applied coverage correction, a significant (\(p \leq 0.05\)) positive trend of 1.2–2.0 km\(^3\) yr\(^{-1}\) over the examined 12-winter period can be observed.

4 Discussion

In Skogseth et al. (2004, 2005), a manual classification of several ERS-2 synthetic aperture radar (SAR) images from 1998–2002 was performed to derive parameters for a wind-driven polynya width model (Haarpaintner et al., 2001), which gives estimates of ice production and brine-enriched shelf water based on satellite imagery, wind data from nearby weather stations and surface hydrography. Ice production was calculated from surface heat balance and includes contributions from open water (frazil ice), thin ice as well as fast and pack ice inside the Storfjorden basin north of 77° N. This setup was later extended to a 33 year record of modeled total ice production covering the winters 1970 to 2002 using model parameters derived from the examined 5-winter period (Skogseth et al., 2005). While the average total ice production for 1998 to 2002 was estimated to 43.6 ± 9.7 km\(^3\), it was slightly lower for the 33 year time series with only 39.9 ± 11.7 km\(^3\). When comparing these numbers to our average estimate of
28.3 ± 8.5 km³ (CC) for 2002/2003 to 2013/2014, one has to keep in mind that Skogseth et al. (2004, 2005) also include ice production under fast- and pack-ice inside the fjord, while our study concentrates on open water and thin-ice areas only. Assuming an average contribution of 25 % from fast-ice and pack-ice areas (Table 3 in Skogseth et al., 2005) and after reducing annually accumulated total ice production accordingly, the average IP (1970 to 2002) inside open water and thin-ice areas of Skogseth et al. (2005) is lowered to approximately 30 ± 9 km³ which is within the here presented SD. Skogseth et al. (2005) give some further information on the interannual variability of ice production within the Storfjorden polynya, although it is stated that the uncertainty for the 33 year time series is increased. The presented 33 year time series shows a slightly negative and non-significant trend of approximately −2 km³ decade⁻¹, while the here presented last 12 winter-seasons show a positive trend of 20.2 km³ decade⁻¹. However, the long-term model-estimates by Skogseth et al. (2005) indicate the presence of multi-decadal fluctuations.

Jardon et al. (2014) developed an ice production model which uses Advanced Microwave Scanning Radiometer – EOS (AMSR-E) sea ice concentration data to derive daily open water fractions. Heat flux calculations over water were performed using ERA interim reanalysis data in a bulk algorithm. In contrast to our results, their estimates of POLA and IP incorporate both frazil ice growth as well as ice growth under ice thicker than 20 cm. In comparison, our results should profit from the enhanced resolution of MODIS and daily derived TIT-distributions. Nevertheless, derived POLA from TIT ≤ 0.2 m in our study compares well with POLA derived from AMSR-E sea ice concentration data. Both wintertime mean POLA and POLA_CC are within the 25th and 75th percentile of the estimated open water area by Jardon et al. (2014) in almost every winter-season, except for 2004/2005 and 2010/2011, where both values derived by MODIS exceed the 75th percentile. Discrepancies in derived total ice production are obvious, but can be partly explained by differences in the regarded time frame of each winter-season. While Jardon et al. (2014) analyze the full period with sea ice in the fjord (roughly October/November to June/July), we focus on the November to March
period. Even if we reduce the presented IP-values by the amount of frazil ice that is formed in the months April–July, which in 2006/2007 (exemplary shown in Jardon et al., 2014) contributed with around 15% to the total volume of frazil ice in this particular winter-season, the time series are differing on average by approx. 40%. Thereby, Jardon et al. (2014) presents higher IP-values in all winter-seasons except 2004/2005 and 2010/2011, but overall the interannual variability is comparable.

The studies by Tamura and Ohshima (2011) and Iwamoto et al. (2014) are facing similar restrictions concerning the spatial resolution of the applied passive microwave data from Special Sensor Microwave Imager (SSM/I) and AMSR-E, which is most apparent in smaller polynyas such as in Storfjorden. In Tamura and Ohshima (2011), an average ice production of $137 \pm 35 \text{ km}^3$ for the period 1992–2007 (September–May) is presented. This value largely exceeds our estimates as well as those by Skogseth et al. (2005) and Jardon et al. (2014), most probably due to the discrepancies in spatial resolution of the input data. More recent numbers by Iwamoto et al. (2014), who use an updated algorithm based on MODIS TIT, AMSR-E and ERA-Interim reanalysis, are also lower than those in Tamura and Ohshima (2011), with the mean annual (also September–May) ice production between 2002/2003 and 2010/2011 being estimated as $47 \pm 5 \text{ km}^3$ (roughly $40 \text{ km}^3$ for November–March; based on presented monthly mean values). A positive trend of $3 \text{ km}^3$ per decade is presented, which is much smaller than our value of $18.7 \text{ km}^3$ per decade based on the same period from 2002/2003 to 2010/2011. Although Iwamoto et al. (2014) provide enhancements in terms of spatial resolution and the inclusion of land-fast ice detection in comparison to Tamura and Ohshima (2011), our estimates are still exceeded in every winter-season. The presented interannual variability is similar to our study, with 2005/2006 and 2008/2009 being the only winter-seasons with a strongly contrasting development. Both Tamura and Ohshima (2011) and Iwamoto et al. (2014) apply noticeably larger polynya masks to derive ice production values in the Storfjorden area, which extend well into the Greenland and Barents Sea regions and far beyond Storfjorden itself. This omission of local characteristics in the Storfjorden basin in addition to a differing base period, which...
spans the months from September to May, could therefore explain part of the difference.

5 Summary and conclusions

In this study, we presented a comprehensive overview of daily thin-ice thickness distributions and resulting thermodynamic ice-production rates for the Storfjorden polynya, located in the southern part of the Svalbard archipelago. The investigation period covers the winter-seasons 2002/2003–2013/2014 from November to March. Our results are complementary to previous studies in the Storfjorden region (e.g. Skogseth et al., 2004, 2005; Hendricks et al., 2011) and underline the importance of this polynya considering the total amount of ice production and accompanied salt release each winter-season, despite its comparatively small spatial extent. Within the polynya, ice thicknesses below 10 cm are dominating in the course of an average winter-season and cover larger areas in the eastern part of Storfjorden. This enables ice-production rates, which sum up to an average value of 28.3 ± 8.5 km$^3$ per winter-season. There is a positive trend in accumulated ice production over the last 12 winter-seasons which contrasts earlier indications of a slightly negative trend prior to 2002 (Skogseth et al., 2005).

Compared to other studies which rely on active and passive microwave remote sensing, the use of MODIS IST has distinct drawbacks considering the effect of clouds, which produce data gaps if correctly identified by the MODIS cloud mask and possibly erroneous IST-values if nighttime clouds remain undetected. By composing daily composites, data gaps in the Storfjorden region were minimized resulting in an average IST-coverage of 82 % within the applied polynya mask. The application of a coverage-correction scheme yielded plausible adjustments of approximately 30 % to the total polynya area and ice production, although its current basic approach offers room for future improvements like e.g. including long-term spatial statistics. Still, this comprehensive data set will be of high value for a variety of climate and ocean applications,
including the provision of quasi-daily high-resolution thin-ice thickness charts for regional climate and ocean models.

Acknowledgements. The authors want to thank the National Snow and Ice Data Center (NSIDC) as well as the European Center for Medium-Range Weather Forecasts (ECMWF) for providing the MODIS Sea Ice product and the ERA-Interim atmospheric reanalysis data. This work was part of the German-Russian cooperation "WTZ RUS: System Laptev Sea: TRANSDRIFT" funded by the Federal Ministry of Education and Research (BMBF) under grant 03G0833D.

Table 2. Accumulated ice production in km$^3$ winter$^{-1}$ and average polynya area (in km$^2$) each winter-season (November to March) in the Storfjorden polynya, together with the interannual average (Mean) and its SD. CC denote values after coverage correction, with relative increase compared to uncorrected values in brackets. All values are calculated within the predefined polynya mask (Fig. 1).

Figure 1. Map of the Svalbard archipelago in western Barents Sea. The study region is located in Storfjorden, which is surrounded by the main island Spitsbergen in the west and Barentsøya/Edgeøya in the east. The applied polynya mask is marked in red, enclosing the Storfjorden basin north of the sill at 77° N. Bathymetric data by Jakobsson et al. (2012) (IBCAO v3.0).
Figure 2. Interannual overview of the daily IST-coverage (%) within the applied polynya mask (compare Fig. 1). Values are derived from daily MODIS IST-composites for the complete investigation period from 2002/2003 to 2013/2014 (November–March).
Figure 3. Relative TIT-distribution in the Storfjorden polynya, with ice thickness classes of 2 cm range (x axis). Input data is based on daily TIT-composites. The bars indicate the mean relative distribution of each thickness class from the total number of TIT ≤ 0.2 m appearances between the winter-seasons 2002/2003 to 2013/2014. Error bars refer to ±1 SD. Besides an overview of the complete freezing season from November to March (c), it is further separated between the months November to December (a) as well as January to March (b).
Figure 4. Early freezing season (November to December) relative frequency distribution of $TIT \leq 0.2$ m for 2002 to 2013, based on daily TIT-composites.
Figure 5. Late freezing season (January to March) relative frequency distribution of TIT ≤ 0.2 m for 2003 to 2014, based on daily TIT-composites.
Figure 6. Hovmoeller diagram of daily POLA_{cc} (TIT ≤ 0.2 m) in the Storfjorden polynya between 2002/2003 and 2013/2014.
Figure 7. Spatial distribution of the interannual mean accumulated IP rate in m winter$^{-1}$. Values are first accumulated for each winter-season from November to March and afterwards averaged for 2002/2003 to 2013/2014.
Figure 8. Annual wintertime accumulated ice production in the Storfjorden polynya, given in km$^3$ winter$^{-1}$. Estimations are based on daily heat flux calculations using the daily derived TIT-composites. Special emphasis is given to the effect of an applied coverage correction (CC). Dotted lines show linear trend estimations for both IP and IP$_{CC}$. 

No CC:
Mean: 21.7 ± 5.9 km$^3$
trend: 1.16, p-value: 0.011

CC:
Mean: 28.3 ± 8.5 km$^3$
trend: 2.02, p-value: 3.9$\times$10$^{-4}$
