Dear Editor,

Thanks for these last comments on our manuscript. All the points mentioned have been accounted for. Find below a point-by-point response to your comments as well as a modified version with changes highlighted in red.

After the re-review, the authors followed the recommendations of the re-reviewer (Cornford) and of the editor and addressed all major issues satisfactorily. Specifically:

- The authors refocused and rephrased the paper now around gridsize dependence (convergence) of MISMIP experiments for the reference model Elmer/Ice.

- For this, they added also a new experiment (also recommended by reviewer Cornford) to investigate the impact of a smooth friction transition at the groundingline which substantially adds to the significance of the paper (which clearly addresses an earlier a point of criticism by the first two reviews). In particular, the obtained result of this additional experiment are not that obvious. The authors also already discussed their new findings with the reviewer Cornford by email (communication asked to be made public in review discussion).

- The numerical implementation of discontinuous friction and the related results are still included but are now well integrated into the mesh-size dependence investigations and the details moved to the supplementary material. The inclusion of this numerical implementation of discontinuous friction is well justified given the role of the Elmer/Ice as a reference model in the MISMIP intercomparison.

- They also shortened the manuscript and resubmitted it as a ‘short-communication’ which is now well justified (novel aspects of numerical model issues relevant for MISMIP’ and of short enough format).

Thus the current manuscript is close to be acceptable. Besides a few very minor points, there remains two more slightly more substantial issues that need addressing before final acceptance which should not be difficult and which are both related to the MISMIP3d experiments (most likely be a result of rearranging of parts of the previous version):

1) Steady state differences (diagnostic), lines 182 to 193: Somehow its is not so clear anymore that you refer to the steady state runs/positions here, this should be clarified near beginning of these two paragraphs. Specifically I would suggest the following:

   Here the comparison is on the first step of the prognostic experiment. This first step consists in finding an initial steady state for the GL from which the perturbation is applied. The text has been clarified.

   • Line 178: it is no longer clear what experiment you mean here for the friction implementation comparison, and do not mean resolution instead of discretization? I assume you mean the steady state case (prognostic), so maybe modify to: ‘First, the steady state geometries for the three friction implementation are compared with similar grid resolutions...’
What is really compared are the steady GL positions for the three friction implementations. This has been clarified.

- Line 180: further I do not really understand what you mean by ...you varied the element size of the mesh along main flow direction..., from above I thought the grid-resolution is the same/fixed. Clarify.

The mesh resolution is not homogeneous along the main flow direction: the smallest elements are only located in a refined zone where the GL is expected to move during the transient simulation and because the steady GL positions are different for the three friction implementations, this refined zone is not located at the same position. This discussion about the mesh was not used further in the discussion and has therefore been removed.

- Line 184: again you refer to the steady states here and 'conduct' seems awkward, so I would rather say '...the three methods result in three different steady state positions....'

Done

2) for the prognostic experiments (probably more substantial), the paragraph from line 194-205 initially heavily refers to the Figure S4 in the supplement, which is not shown however in the main text. This is not ideal, as details of this figures are described that one is not able to follow at all without the figure. And I think these details are also not necessary here, the essence of the paper is on gridsize dependence now (and the method comparison is useful but not the major part). I assume the authors could not add another figure due to the short communication format (space) and thus moved it to the supplement.

I suggest to the authors two options of how they could address this problem:

We agree and have adopted option 1 as suggested by the editor. The paragraph has been summarised and most of the text has been moved in the supplementary. The legend of Fig. 3 now makes reference to the 3 figures in the supplementary.

-Option 1 (which is my much preferred one): Reduce this paragraph to a summary of the main message from the figure: e.g. ...In the P75S experiment (for the coarse transverse resolution Ny=20) we found that the results in transient responses (relative to the initial positions) differ substantially between the three methods (see supplement Fig. S4), also for the reversal of the perturbation. You then continue with your paragraph on line 206: ...Such large differences in transient....

Maybe you could add a little description/discussion paragraph in the supplement if you are keen to explain these details more.

-Option 2 (but not that ideal): you move Fig. S4 to the main text as Fig. 3. But then I would expect some substantial shortening of the text on the diagnostic and transient part Lines 178-205.
Further I would clarify a bit what is shown in Fig. 3 by changing the text on line 213 to:
'The results for lateral resolutions with Ny=20, Ny=40 and Ny=80 grid points are shown in the Supplementary Figures S4, S5 and S6 and the differences from such lateral resolution visualized relative to the highest resolution Ny=80 in Figure 3.’ …

Done.

Minor points

Line 41-43: i would add before the two questions (on line 41): 'This raises the following questions. Is the …'

Done.

Line 65: is there not a 'problem' missing here: ‘….contact problem between…’ (you can not solve a contact slone, but a contact problem.

Done.

Line 97: should it not rather say ‘formulation' instead of ‘formalism'

Done.

Line 124: ‘result’ (plural) and nor ‘results'

Done.

Line 124: I would say ‘different flow approximations' instead of ‘different models'

Done.

Line 127: please check with the Cornford whether he is happy with this formulation of the personal communication. I will try and add the email conversation to him to the review discussion part on TCD.

Stephen Cornford has been informed about the personal communication and do agree with its formulation (see his email). I have also added the possibility that the differences are induced by different typical length for the friction decay.

Line 133-138: this is a very long sentence and thus hard to follow, break it up.

Done.

Line 168: remove the ‘then’

Done.

Line 189: ‘...it should also be noted that…’

Done.
Line 225: ‘purpose’ does not seem the right word here: maybe ‘reasons’ is better

 Done.

Line 234: ‘...different friction EVOLUTION....’ is awkward (evolution usually refers to time ...), maybe change to ‘....different friction transition schemes...’

 Done.

Line 244: 'In doing so,...' (rather than 'so doing').

 Done.

Line 250: ‘...using mesh resolutions that are...’

 Done.

Comments to Supplementary material:

p.4 line 2: verb should be in plural: ‘...models do not ...’

 Done.

p.4 line 11-12: you refer to a discussion on the transient case (at least this is what I expected) but there is no such discussion in the supplement, there is only fig. S4. So add such a discussion or delete this reference (but leave reference to Fig. S4).

 Make sure the reference list and figures are kept apart (first figures then reference list).

 Done.
Brief communication: Impact of mesh resolution for MISMIP and MISMIP3d experiments using Elmer/Ice

Abstract. The dynamical contribution of marine ice sheets to sea level rise is largely controlled by grounding line (GL) dynamics. Two marine ice sheet model intercomparison exercises, namely MISMIP and MISMIP3d, have been proposed to the community to test and compare the ability of models to capture the GL dynamics. Both exercises are known to present a discontinuity of the friction at the GL, which is believed to increase the model sensitivity to mesh resolution. Here, using Elmer/Ice, the only Stokes model which completed both intercomparisons, the sensitivity to the mesh resolution is studied from an extended MISMIP experiment in which the friction is continuously decreasing over a transition distance and equals to zero at the GL. Using this MISMIP-like setup, it is shown that the sensitivity to the mesh resolution is not improved for a vanishing friction at the GL.

For the original MISMIP experiment, i.e. for a discontinuous friction at the GL, we further show that the results are moreover very sensitive to the way the friction is interpolated in the close vicinity of the GL. On the light of these new insights, and thanks to increased computing resources, new results for the MISMIP3d experiments obtained for higher resolutions than previously published are made available for future comparisons as Supplement.
1 Introduction

Marine terminating glaciers in Antarctica and Greenland control the dynamical contribution of these ice sheets to sea level rise. Among the processes at play, the retreat of the grounding line (GL) has a major impact on this dynamical contribution. Accurate modelling of GL dynamics is therefore a precondition for prognostic simulations of the future of ice sheets in a warming climate (Durand and Pattyn, 2015). Previous works have emphasised the importance of the mesh resolution around the GL (Vieli and Payne, 2005; Durand et al., 2009a, b; Pattyn et al., 2012; Durand and Pattyn, 2015) and how the friction is interpolated in the vicinity of the GL (Gladstone et al., 2012; Seroussi et al., 2014; Leguy et al., 2014). Two recent intercomparison exercises were designed to compare and test the ability of ice-sheet models to resolve the advance and retreat of the GL based on different perturbations. MISMIP was dedicated to two-dimensional flow line geometry (Pattyn et al., 2012) and used an analytical solution (Schoof, 2007), whereas MISMIP3d was a fully three-dimensional setup (Pattyn et al., 2013).

Elmer/Ice was the only Stokes model to complete the MISMIP experiment 3a (Pattyn et al., 2012) and it was one of only two Stokes models to perform the whole MISMIP3d experiments (Pattyn et al., 2013). Moreover, in the latter intercomparison exercise, the diagnostic experiment P75D was directly build from the geometry obtained with Elmer/Ice after the 100 year perturbation experiment. As the only Stokes model to perform the two intercomparison exercises, Elmer/Ice results are currently used as references for comparison with other models based on lower order Stokes equations (e.g. Feldmann et al., 2014). The results of the MISMIP and MISMIP3d intercomparisons obtained with Elmer/Ice are also used as benchmarks to test Stokes models during their development.

Both MISMIP and MISMIP3d intercomparisons have confirmed that, except the heuristic approach prescribing the boundary layer flux at the grounding line (Schoof, 2007), all other approaches require a fine resolution close to the grounding line to accurately describe its dynamics. One common feature of both MISMIP and MISMIP3d is the use of a constant sliding parameter over all the grounded part. Doing so, the friction at the GL presents a discontinuity, which is believed to increase the model sensitivity to the mesh size at the GL. This raises the following questions. Is the sensitivity of models to mesh resolution specific to the discontinuous friction imposed in both MISMIP and MISMIP3d? Are there alternative numerical methods that would decrease the sensitivity to the mesh resolution for a given setup?

Two recent contributions started answering these questions, the first by adopting a smoothed friction upstream the GL (Leguy et al., 2014) and the second by introducing a sub-grid evaluation of the GL position (Seroussi et al., 2014). From a modified MISMIP setup and using the shallow shelf approximation (SSA) implemented on a fixed grid, Leguy et al. (2014) have shown that introducing a smooth transition between finite basal friction in the ice sheet and zero basal friction in the ice shelf significantly improves the numerical accuracy of the model. In other words, the sensitivity of the GL dynamics to the grid size is shown to be significantly reduced when the friction continuously
decreases to zero upstream the GL. Importantly, by smoothing the friction, the physical problem is modified and will result in a more retreated steady state GL position than the original MISMIP one. However, a smooth friction vanishing at the GL is certainly more realistic than a discontinuous one since one expects that the effective pressure is null at the GL. Using the MISMIP3d experiments, Seroussi et al. (2014) compared various parameterisations of the GL position for a finite element (FE) SSA model. Using the SSA, the GL position is directly evaluated from the floatation criterion and can therefore be located at any point of the domain and not only at the element nodes. In this way, the basal friction can be evaluated with a subgrid resolution. Their results, for a discontinuous friction at the GL (MISMIP3d), showed that sub-element parametrisation of the GL significantly reduces the sensitivity of the results to the mesh size at the GL. The proposed methods, by estimating the GL position at a subgrid scale, acts similarly than an increased mesh resolution around the GL, but without the numerical cost associated with remeshing when the GL is moving.

For a Stokes model, the solution proposed by Leguy et al. (2014) might be an alternative as, unfortunately, the sub-element parametrisation implemented by Seroussi et al. (2014) in their SSA model cannot be applied to solve the contact problem between the ice and its bed. Indeed, the contact condition can only be evaluated at the element nodes. In other words, for a Stokes model, the two alternatives are to either solve a modified problem which would be less sensitive to mesh resolution or improve the accuracy of the model by increasing the mesh resolution. Obviously, the former solution cannot be applied if one wants to solve the original MISMIP and MISMIP3d experiments.

The aim of this brief communication is to study, for the Elmer/Ice Stokes model, the impacts on the accuracy of a smooth transition of the friction at the GL and of the way the friction is implemented at the GL. It is first shown that for the Stokes solution, contrary to what is found by Leguy et al. (2014) for SSA, introducing a smooth transition of the friction at the GL has no significant effect on the sensitivity of the model to the grid size. In the case of a discontinuous friction at the GL, we then present three possible FE implementations of the friction at the GL and show that these different implementations result in significant differences in terms of GL dynamics for the well-defined MISMIP and MISMIP3d experiments. All the newly obtained MISMIP 3d results are made available in the Supplement for future model comparisons.

2 Sensitivity to mesh resolution and friction implementation

This section presents results on the sensitivity to the mesh resolution using a flow line configuration. For that purpose, the GL dynamics is studied using a set up adapted from experiment 3a of the MISMIP intercomparison exercise (Pattyn et al., 2012). Experiment 3a assumes an overdeepened bedrock, a non-linear Weertman friction law and that the GL is evolved by step changes of the ice fluidity parameter. Previous works have shown that steady-state position of GL could differ slightly depending on whether it is obtained from advancing or retreating GL, but that this difference de-
creased with an increase in mesh resolution [Durand et al. (2009a)]. For a given mesh discretization, the accuracy of the model is therefore assessed as the difference between the retreat and advance steady positions.

Basal friction in the experiment 3a of MISMIP is imposed on the form of a non-linear Weertman sliding law, linking the basal shear stress and the sliding velocity:

\[ \sigma_{nt} + C u_n^m = 0 \]  
\[ \tag{1} \]

The original MISMIP 3a setup assumes a constant friction parameter \( C \) where the ice is grounded, i.e. for \( x \leq x_G \), and perfect sliding at the interface between the ice and the ocean, i.e. for \( x > x_G \), \( x_G \) being the GL position and assuming the horizontal velocity to be positive.

In order to smooth the friction upstream the GL, [Leguy et al. (2014)] have proposed a simple parametrization of the effective pressure, the overburden pressure minus the water pressure, coupled with a Coulomb-type friction law. Here, following their idea, but assuming a simpler formulation, the friction parameter \( C \) of the original MISMIP experiment is modified as follow:

\[ C^* = C \quad \text{if} \quad x \leq x_G - L \]  
\[ \tag{2} \]

\[ C^* = C(x_G - x)/L \quad \text{if} \quad x_G - L \leq x \leq x_G \]  
\[ \tag{3} \]

\[ C^* = 0 \quad \text{if} \quad x \geq x_G \]  
\[ \tag{4} \]

Doing so, the friction is linearly decreasing over a distance \( L \) from \( C \) to 0 at the GL. Note that the physical problem is then modified and the steady solution for a given \( L > 0 \), as well as the transient phases, are expected to be different than those of the original MISMIP. When \( L = 0 \), the problem is equivalent to the original MISMIP and the friction presents a discontinuity at the GL. Because \( C^* \) is estimated at the mesh nodes, and then interpolated on the element using the FE basis function, the same solution is expected for any \( L \) lower or equal to the grid size.

The same type of mesh than the one used for producing the Elmer/Ice MISMIP results is used, with an evolving resolution along the flow direction (see [Durand et al. (2009a)] for more details). The discretization therefore refers to the minimum horizontal mesh size in the close vicinity of the GL. The model accuracy is studied for four mesh sizes, from 200 to 25 m, and \( L = 60 \) and \( L = 500 \) m. Starting from the ice-sheet geometry for step 1 and step 5 of experiment 3a (see [Pattyn et al. (2012)] for more details), the ice fluidity for step 4 is then applied and the geometry is evolved until a steady state is obtained, one in advance (from step 1 to step 4) and one in retreat (from step 5 to step 4).

From Figs. 1 and 2, one can clearly see that for \( L > 0 \) (red and black curves), the problem is modified and so are the GL steady positions. The longer the length of the decreased friction, i.e. the larger is \( L \), the less advanced the GL steady position. Simulations for \( L = 1000 \) m were even found to have their steady positions upstream the initial Step 1 position and cannot be used therefore to test the model accuracy as both steady solutions are obtained in retreat mode. As show in Fig. 2b,
and contrary to what was found by Leguy et al. (2014), no improvement of the model accuracy is found when \( L \) is increased. For these simulations, the largest errors are even found for \( L = 500 \) m, but with no significant differences from the other simulations. The reasons that might explain this different behaviour are multiple, but most probably result in the two different flow approximations (SSA versus Stokes) and/or the adopted formulation to smooth the friction upstream the GL (form of the smoothing function and/or the typical length for the friction decay). On the other hand, these results seems to be in line with the ones obtained by Cornford with BISICLES (Cornford, personal communication, see the review material of this paper).

Moreover, in the case of a discontinuous friction at the GL (\( L = 0 \)), three different numerical implementations of the friction in the close vicinity of the GL have been tested. The three implementations are presented in details in the Supplement. The first is assuming that the GL defines the last grounded (LG) nodes and that friction is applied up to the nodes belonging to the GL. In the second, the nodes belonging to the GL are assumed to be the first floating (FF) nodes and are already freely slipping. The third one reproduces exactly the discontinuity (DI) of the friction at the nodes belonging to the GL. For the DI implementation, the friction at these nodes is only applied if integrating over an element where all other nodes are also in contact with the bedrock but a free slip condition is applied if the node belongs to an element where at least one node is in contact with the ocean. The three implementations are illustrated in a two-dimensional flow line configuration in Fig. S1 of the Supplement. Note that as far as \( L > 0 \), all three implementations are equivalent and give the same results. Despite the DI implementation being certainly the most physical, up to now, all the published Elmer/Ice results were obtained using the LG method (Durand et al., 2009a, 2011; Gagliardini et al., 2010, 2013; Favier et al., 2012, 2014; Drouet et al., 2013; Gudmundsson et al., 2012; Pattyn et al., 2012, 2013; Krug et al., 2014). Note that other possible implementations, such as a constant friction value per element, would certainly conduct to other results.

For \( L = 0 \), the three friction implementations (LG, DI and FF) converge to the same, most advanced, steady state position when the mesh size is decreased. Nevertheless, as shown in Figs. 1 and 2a, for a given mesh size, differences on the steady GL positions from the three methods are of the same order than differences from advance to retreat for a given method. The LG method leads to the most advanced GL, the FF method to the least advanced GL and the DI method to an intermediate GL position. For a 200 m discretization, the difference between the LG and FF methods is larger than 15 km in both advance and retreat. The DI position is almost exactly half way between the LG and FF positions. With a 25 m resolution at the GL, these differences are reduced to less than 2 km in both advance and retreat. For the purpose of comparison, with a given method, the difference between advance and retreat is around \( \approx 25 \) km at the resolution of 200 m and is decreased to less than 3 km at a resolution of 25 m.

Finally, Fig. 2a also shows the published Elmer/Ice GL position obtained in advance from step 3 to step 4 in Pattyn et al. (2012). This solution was produced using the same discretisation of 200 m.
at the GL, but not exactly the same mesh. Despite the same discretisation at the GL, there is a 3 km
difference with the new LG solution for \( L = 0 \). In line with Durand et al. (2009b), these differences
illustrate the sensitivity of the GL position not only to the mesh resolution at the GL, but also to
the other mesh characteristics, and more specifically how strongly the mesh resolution is reduced
downstream and upstream the GL.

As expected theoretically, the MISMIP flow line study confirms that, despite a high jump in fric-
tion at the GL, all three implementations of the friction converge to an identical solution as the mesh
resolution is improved, but can lead to significantly different solutions for a too coarse mesh. On
the light of these significant differences between the three friction implementations for the MISMIP 3a
experiment, the following section aims to quantify these differences for the MISMIP3d experiments.

### 3 Sensitivity to the lateral discretisation of MISMIP3d experiments

In this section, the three numerical implementations of the friction are compared using the progno-
stic experiments of MISMIP3d. New results for the diagnostic experiment P75D of MISMIP3d are
also presented in Section 2 of the Supplement. The prognostic experiment in MISMIP3d is decom-
posed in three steps. First, assuming no lateral variation in \( y \), a steady state geometry is obtained
for each model. In the second step, P75S, a Gaussian sliding perturbation is introduced precisely at
the grounding line and centred on the axis of symmetry at \( y = 0 \) km. This constant perturbation is
applied for the next 100 years. Finally, during the last step, P75R, the perturbation is removed and
the GL moves back to its initial steady position. Only the first 100 years of the removal are studied.
Note that for the grounding line to get back to its initial steady state position might take much longer
than 100 years as the behaviour in advance and retreat is not symmetrical.

First, the steady GL positions for the three friction implementations are compared using meshes
with the same resolution at the GL than the one used to obtain the LFA results in Pattyn et al. (2013).
As expected from the previous section, the three methods result in three different GL positions \( x_{G0} \),
the LG solution being more advanced by \( \approx 7 \) km in comparison to the FF one (see Table S1 in
the Supplement). It should be noticed that this distance is similar to the one obtained between the
LG solution and the LFA solution published in Pattyn et al. (2013), using the same discretisation
at the GL but not exactly the same mesh. This gives again an indication on how the results are
sensitive to the mesh, and not only in the vicinity of the GL. It should also be noted that these
differences stay much smaller than the differences obtained between the Stokes and SSA solutions
\( x_{G0} \approx 525 \) km for the Stokes against \( x_{G0} \approx 605 \) km for the SAA (Pattyn et al. 2013; Seroussi
et al., 2014; Feldmann et al., 2014). In what follows, the transient response is discussed relative to
the steady GL position \( x_{G0} \), obtained for each friction implementation.

The displacement of the GL relative to its initial steady position is found to be substantially differ-
ent for the three friction implementations, for both the perturbation experiment P75S and the reversal
of the perturbation experiment P75R (see Fig. S4 in the Supplementary). Such large differences for
the transient response of the three methods can only be explained by a too coarse mesh. The steady
solution being reasonably close, and independent of the lateral discretisation of the mesh (no trans-
verse variation of any field so that the steady GL is a straight line perpendicular to the $x$ direction),
the source of discrepancy for the transient response certainly arises from the lateral discretisation.
The number of lateral elements $N_y$ is only 20 for the previous simulations. The sensitivity of the
transient response to the lateral discretisation is investigated by running the same experiment with
two finer lateral mesh resolutions, everything else being the same. The results for lateral resolutions
with $N_y = 20$, $N_y = 40$ and $N_y = 80$ elements in the lateral direction are presented in the Supple-
mentary Figs. S4, S5 and S6, respectively. Figure 3 shows the differences from such lateral resolution
visualized relative to the highest resolution $N_y = 80$. As can be seen from Fig. 3, differences in the
transient response of the three methods are significantly decreased when the lateral mesh refinement
is increased. Nevertheless, even with the finest mesh ($N_y = 80$), the difference between the methods
stays relatively important ($\approx 5$ km between LG and FF at the end of the perturbation experiment,
but to be compared to 17 km for $N_y = 20$). Figure 3 indicates that the difference for the three meth-
ods between the higher resolution ($N_y = 80$) and the two other mesh refinements ($N_y = 40$ and
$N_y = 20$) is smaller for the DI method than the two others. In other words, the DI method seems to
be less sensitive to the mesh refinement than the two other methods, certainly because it gives an
intermediate solution whatever the mesh resolution. This is one more reason that justify that the DI
method should be preferentially adopted for future works. Note however that the decrease in mesh
sensitivity is not as high as for the subgrid methods proposed for the SSA (Seroussi et al., 2014).

Higher lateral discretisation were not further explored for computing resource reasons, but this
study clearly indicates that, as expected theoretically and shown in the previous section using the
flow line setup MISMIP, the difference between the three implementations is decreased as the mesh
resolution is increased. Published LFA results (Pattyn et al., 2013) were obtained with a lateral
discretisation of $N_y = 20$ elements, which was certainly insufficient as shown by these new results
using 40 and 80 lateral elements. For further comparisons, we recommend to use the more accurate
results presented in Fig. S6 and provided as Supplement.

4 Conclusions

In this paper, the sensitivity to the mesh resolution of the dynamical response of the GL is studied for
different friction transition schemes upstream the GL. Contrary to Leguy et al. (2014), a smoother
friction vanishing at the GL is not found to improve model sensitivity to mesh resolution. Explaining
the reasons of such different behaviour is beyond the scope of this paper, but we encourage further
works in that direction with various models and various smoothing functions for the friction upstream
the GL. Having the friction smoothly decreasing to zero at the GL is certainly more realistic, as one
expect the effective pressure to vanish at the GL. Therefore, even if it might present no advantage in term of mesh sensitivity, such more realistic friction distribution should be preferred for future model intercomparisons.

In the case of a discontinuous friction, as in the MISMIP and MISMIP3d experiments, we have presented three possible implementations of the friction at the GL for a finite element formulation of the Stokes equations. So far, in all the applications using Elmer/Ice, it was assumed that the friction is applied up to the GL using the LG method. In doing so, the first elements immediately downstream from the GL undergo a little friction even if being in contact with the ocean. We have shown that the treatment of the friction at the GL has a strong influence on both the velocity field and on the resulting GL dynamics for the mesh resolutions that were used to produce the MISMIP and MISMIP3d results. As expected theoretically, differences between the three implementations are shown to decrease as the mesh resolution is increased, but these differences remains substantial when using mesh resolutions that are numerically affordable for usual 3D applications. Even for the smallest refinements accessed for the three-dimensional test case, differences are still observed. However, these differences are much smaller than those between Stokes and lower-order models. This give an indication on the model error to be expected when performing GL dynamics simulations with a Stokes model. Moreover, using MISMIP3d experiment, the lateral refinement is shown to have also a significant influence on the transient behaviour.

In the case of a discontinuous friction at the GL, we finally recommend to use the discontinuous DI implementation which is certainly the most realistic and the less sensitive to the mesh refinement of the three. We also recommend to use these newly published results with finer mesh resolutions for future model comparison.

In (a), the large white star corresponds to the published GL position for step 4 of experience 3a in [Pattyn et al. (2012)] and the dot-dashed line is the Schoof (2007) solution.

Figure 3. Influence of lateral resolution from experiment MISMIP3d P75S and P75R: evolution of the absolute differences in km between the highest resolution ($N_y = 80$) and the two others ($N_y = 40$ continuous line and $N_y = 20$ dashed line) for the three different methods: LG (brown), DI (purple) and FF (blue), on the symmetry axis ($y = 0$; thick curves) and on the free-slip boundary ($y = 50$ km; thin curves). The initial results used to plot this figure are presented in the Supplementary Figs. S4, S5 and S6 for lateral resolutions $N_y = 20$, $N_y = 40$ and $N_y = 80$, respectively.
