13 Abstract

14 Sea-ice concentrations derived from satellite microwave brightness temperatures are less
15 accurate during summer. In the Arctic Ocean the lack of accuracy is primarily caused by melt
16 ponds but also by changes in the properties of snow and the sea-ice surface between melt
17 ponds. We investigate the sensitivity of eight sea-ice concentration algorithms to melt ponds
18 by comparing sea-ice concentration with melt-pond fraction. We derive gridded daily sea-ice
19 concentrations from microwave brightness temperatures of summer 2009. We derive the daily
20 fraction of melt-ponds, open water between ice floes and ice-surface fraction from
21 contemporary Moderate Resolution Spectroradiometer (MODIS) reflectance. We only use
22 grid cells where MODIS sea-ice concentration, which is melt-pond fraction plus ice-surface
23 fraction, exceeds 90%. For one group of algorithms, e.g., Bristol and Comiso Bootstrap
24 frequency mode (Bootstrap_f), sea-ice concentrations are linearly related to the MODIS melt-
25 pond fraction quite clearly after June. For other algorithms, e.g., Near90GHz and Comiso
26 Bootstrap polarization mode (Bootstrap_p), this relationship is weaker and develops later in
27 summer. We attribute the variation of the sensitivity to the melt-pond fraction across the
28 algorithms to a different sensitivity of the brightness temperatures to snow-property
29 variations. We find an *under-estimation* of the sea-ice concentration by between 14%

1 (Bootstrap_f) and 26% (Bootstrap_p) for 100% sea ice with a melt-pond fraction of 40%. The
2 under-estimation reduces to 0% for a melt-pond fraction of 20%. In presence of *real* open
3 water between ice floes, the sea-ice concentration is *over-estimated* by between 14%
4 (Bootstrap_f) and 26% (Bootstrap_p) at 60% sea-ice concentration and by 20% across all
5 algorithms at 80% sea-ice concentration. None of the algorithms investigated performs best
6 based on our investigation of data from summer 2009. We suggest, that those algorithms
7 which are more sensitive to melt ponds, could be optimized easier because the influence of
8 unknown snow and sea-ice surface property variations is less pronounced.

9 10 **1 Introduction**

11 Sea-ice area and extent are derived from data of the sea-ice concentration, i.e. the fraction of a
12 given area of the ocean covered with sea ice. Observations of the brightness temperature by
13 satellite passive microwave sensors have been the backbone for sea-ice concentration retrieval
14 since over 35 years because these are independent of daylight and quite insensitive to the
15 cloud cover. These sensors used for sea-ice concentration retrieval measure the brightness
16 temperature at window frequencies between 6 GHz and ~ 90 GHz at both, vertical and
17 horizontal polarization, at a constant incidence angle of $\sim 53^\circ$ which we use for the present
18 paper. Numerous sea-ice concentration retrieval algorithms have been developed during the
19 past decades (see e.g. Ivanova et al., 2015). All algorithms exploit in some way the contrast in
20 the microwave brightness temperature between open water and sea ice to retrieve the sea-ice
21 concentration. During cold conditions, i.e. as long as freezing conditions prevail, sea-ice
22 concentrations are retrieved with these algorithms as accurate as 2% to 5% for the near 100%
23 ice cover (Ivanova et al., 2015, 2014; Andersen et al., 2007; Meier, 2005). However, during
24 melting conditions the retrieval accuracy is reduced substantially and sea-ice concentrations
25 can be biased low compared to the actual sea-ice concentration (Ivanova et al., 2013; Rösel et
26 al., 2012b; Comiso and Kwok, 1996; Cavalieri et al., 1990).

27 One potential reason for the reduced accuracy is the change in microphysical properties inside
28 the sea ice, for instance, the desalination of the sea ice during the melt process or the flushing
29 of air voids in multiyear ice with melt water and other melt processes for example described
30 in Scharien et al. (2010). Another potential reason is the change in surface properties of the
31 sea ice. The three key surface features of summer melt on Arctic sea ice are a metamorphous,
32 wet snow cover, a porous, wet sea-ice surface, and melt ponds. During summer, the snow
33 cover on sea ice is usually wet or even saturated with melt water (Garrity, 1992). Its density is

1 usually considerably larger during summer than during winter (Warren et al., 1999; Maykut
2 and Untersteiner, 1971). Diurnal freeze-thaw cycles, i.e. episodes of intermittent melting and
3 refreezing of the snow, which is a common phenomenon during late spring, result in an
4 increase of the snow grain size.

5 Wet snow is an efficient absorber of microwave radiation and has a microwave emissivity
6 close to 1. It can effectively block microwave emission from underneath and thereby masks
7 differences in volume scattering between first-year and multiyear ice. Therefore microwave
8 brightness temperatures of sea ice covered with wet snow usually are close to its physical
9 temperature during melt (e.g. Stiles and Ulaby, 1980; Eppler et al., 1992; Hallikainen and
10 Winebrenner, 1992; Garrity, 1992).

11 During the thaw phase of freeze-thaw cycles, coarse-grained snow can be regarded to behave
12 similar to wet snow due to its wetness. During the freeze phase, however, when it is dry, it
13 absorbs less microwave radiation than wet snow and there is more scattering from within the
14 snow. Therefore, dry coarse-grained snow does not block or mask microwave emission and
15 volume scattering differences of the sea ice and/or snow underneath as efficiently as wet snow
16 does. The amount of volume scattering depends on microwave frequency and polarization,
17 and on the vertical location of the coarse-grained snow layers relative to the snow surface.
18 Because the electromagnetic wavelengths are closer to the snow grain size at higher
19 frequencies, i.e. at 37-90 GHz, volume scattering in snow is larger for the higher than the
20 lower microwave frequencies (Fuhrhop et al., 1998; Eppler et al., 1992; Hallikainen and
21 Winebrenner, 1992; Gogineni et al., 1992). In Tables 1 to 3 we give sensitivities of brightness
22 temperatures with respect to changes in snow wetness, density, and grain size. These tables
23 are not meant to be exhaustive. Instead we will use the sensitivities for our discussion of the
24 results (section 4).

25 Melt ponds are puddles of melt water on top of sea ice. They form during summer from
26 melting snow and sea ice. Their areal fraction, size and depth is determined by the onset,
27 length and severity of the melting season, the sea-ice type and topography, and the snow-
28 depth distribution at the beginning of melt (Landy et al., 2014; Polashenski et al., 2012;
29 Petrich et al., 2012; Eicken et al., 2004; Perovich et al., 2002). The melt-pond water salinity is
30 close to zero ppt. Typically, the melt-pond fraction on Arctic sea ice varies between 10% and
31 40% but can also exceed 50%, for instance, early in the melt season or on land-fast sea ice
32 (Webster et al., 2015, JGR-O; Divine et al., 2015, TC; Landy et al., 2014; Polashenski et al.,

1 2012,; Sankelo et al., 2010, POLRES; Tschudi et al., 2001 (JGR-D; Yackel and Barber, 2000;
2 Fetterer and Untersteiner, 1998, JGR-O).

3 The penetration depth of microwave radiation at the frequencies used here, i.e. between 6 and
4 89 GHz, into liquid water is in the order of one millimeter (Ulaby et al., 1986). We use the
5 penetration depth here as the depth from which most of the microwave radiation originates.
6 Because of the above-mentioned very low penetration depth, a water layer with a depth of a
7 few millimeters is opaque enough to completely block the microwave signal from the sea ice
8 underneath. A melt pond on sea ice has the brightness temperature signal of open water and is
9 therefore indistinguishable from open water in cracks or leads between the sea-ice floes
10 (Gogineni et al., 1992; Grenfell and Lohanick, 1985). At 6 GHz and higher frequencies the
11 signature of fresh water and salt water are indistinguishable. Satellite microwave sensors
12 which have been used for sea-ice concentration retrieval allow for footprint sizes between ~ 5
13 km and ~ 70 km. Melt ponds, cracks and leads are therefore sub-footprint size surface features
14 and cannot be resolved individually. A space-borne brightness temperature measurement of a
15 mixed scene is therefore composed of contributions from the open water, i.e. cracks, leads,
16 melt ponds, and from the (snow covered) sea ice. This has two main consequences for a sea-
17 ice concentration product computed from such coarse resolution satellite measurements. The
18 sea-ice concentration in the presence of melt ponds is likely to be underestimated – because
19 melt ponds are seen as open water. Whether the footprint contains, for example, A) 100% sea
20 ice with 40% melt ponds or B) 60% sea ice with 40% open water from leads and openings, is
21 ambiguous. In both cases satellite microwave radiometry retrieves 60% sea-ice concentration
22 because the net sea-ice *surface* fraction of sea ice in the grid cells is 60%. If during summer, a
23 sea-ice concentration retrieval algorithm over-estimates the net sea-ice surface fraction in case
24 A, for example because of a specific summer-time microwave signature of the sea ice, and
25 provides, e.g., ~90% sea-ice concentration, then the same algorithm would most likely also
26 overestimate the net sea-ice surface fraction in case B. The algorithm would hence *under-*
27 *estimate* the actual sea-ice concentration in case A but *over-estimate* the actual sea-ice
28 concentration in case B.

29 This has consequences for climate research. For example, the sea-ice area, which is defined as
30 the sum of the area of all sea-ice covered grid cells weighted by the sea-ice concentration, will
31 be computed correctly from case A) but will be under-estimated from case B). Approaches
32 have been developed, which permit to derive the melt-pond fraction on sea ice from satellite
33 observations in the visible/near-infrared frequency range (Istomina et al., 2015a, 2015b; Zege

1 et al., 2015; Rösel et al., 2012a). Their results could be used to correct the above-mentioned
2 ambiguity by quantifying how much of the open water seen (30% in the example above) is
3 actually caused by melt ponds. However, the time-series of melt-pond fraction data computed
4 so far (2002-2009 and 2002-2011) are too short to apply such a correction for the entire 35
5 years long sea-ice concentration data set from satellite microwave radiometry. In addition,
6 such data may have limitations due to cloud cover and the viewing geometry at high latitudes
7 (see sub-section 2.1).

8 The ambiguity in the actual surface properties behind the sea-ice concentration value of 60%
9 in the example above is also challenging for the initialization and evaluation of numerical
10 models, and the assimilation of sea-ice concentration data into such models. An unambiguous
11 sea-ice concentration is required for, e.g., the correct computation of the sea-ice volume. In
12 the terminology of the more advanced thermo-dynamic and dynamic sea-ice models or model
13 components which treat leads and melt ponds separately (e.g. Holland et al., 2012, JC; Flocco
14 et al., 2010, JGR-C), the fraction of sea ice covering the open ocean is called sea-ice
15 concentration and includes melt ponds. The fraction of the latter is given separately as the
16 area of the sea-ice surface covered by melt ponds and is called melt-pond fraction. It is
17 obvious, that such models would have difficulties using a sea-ice concentration product which
18 is biased like described above for cases A and B. Even numerical models, which are not as
19 advanced and which do not treat melt ponds separately, would have difficulties to use such a
20 product.

21 This calls for a better quantification of the uncertainty and/or of potential biases in the sea-ice
22 concentration. How sensitive are present-day sea-ice concentrations algorithms to the melt-
23 pond fraction? How do these algorithms differ with respect to the expected bias due to melt
24 ponds and how can we explain these differences? We hypothesize that microwave brightness
25 temperatures and sea-ice concentrations derived from them change linearly with the increase
26 in surface-water fraction or the decrease in net sea-ice surface fraction due to melt ponds. To
27 the authors' best knowledge, an inter-comparison of different algorithms which incorporates
28 contemporary information of the melt-pond fraction and an independent sea-ice concentration
29 estimate, as is the aim of this study, has not previously been carried out.

30 We illustrate how satellite microwave brightness temperature measurements vary with the net
31 sea-ice surface fraction derived from satellite visible/near-infrared (VIS/NIR) imagery. We
32 compare sea-ice concentration obtained with different sea-ice concentration retrieval
33 algorithms from these brightness temperatures with the sea-ice concentration and with the net

1 sea-ice surface fraction from VIS/NIR imagery. We isolate the influence of melt-pond
2 fractions on the net sea-ice surface fraction by limiting our analysis to VIS/NIR imagery sea-
3 ice concentrations > 90%. We demonstrate how these brightness temperatures change with
4 progression of melt and discuss the implications of this change for sea-ice concentration
5 retrieval.

6 The paper is organized as follows. The next section (2) describes the data sets and methods
7 used for the inter-comparison of brightness temperatures and sea-ice concentrations derived
8 with several algorithms and the melt-pond fraction. In section 3 we are going to present the
9 results of this inter-comparison which we discuss in section 4. Section 5 concludes the
10 findings.

11

12 **2 Data and Methods**

13 The paper focuses on the melt season, i.e. months June, July, and August, of the year 2009.
14 The spatial domain of our investigations is a region of the Arctic Ocean (see Figure 1) and it
15 is determined by the area and data which we chose to compute the sea-ice cover parameters
16 from satellite VIS/NIR imagery, described in the following sub-section 2.1.

17 **2.1 Sea-ice parameters from VIS/NIR satellite imagery**

18 **2.1.1 Data sets and methodology**

19 We derive the open water fraction, melt-pond fraction, and net sea-ice surface fraction from
20 reflectance measurements of the Moderate Resolution Imaging Spectroradiometer (MODIS)
21 aboard the Earth Observations Satellite TERRA. We use the “*MODIS Surface Reflectance*
22 *daily L2G Global 500 m and 1 km*” - product (MOD09GA,
23 <http://reverb.echo.nasa.gov/reverb/>). We obtain the L2G data on the sinusoidal tile grid used
24 for MODIS L2 data from http://modis-land.gsfc.nasa.gov/MODLAND_grid.html. We project
25 the MODIS reflectance data together with land, cloud, and ancillary information onto the
26 NSIDC polar stereographic grid with tangential plane at 70°N with a grid resolution of 0.5
27 km. Subsequently, we use all re-projected tiles to compose an Arctic mosaic of the MODIS
28 wavelength bands 1: 459-479 nm, 3: 620-670 nm, and 4: 841-876 nm. We apply a spectral
29 un-mixing approach to classify the fractions of open water (between the ice floes), melt
30 ponds, and sea ice, which can be barren or snow covered. For this we use typical reflectance
31 values of these surface types in the above-mentioned wavelength bands (Tschudi et al., 2008).
32 The methodology is explained in more detail together with validation results in Rösel et al.

1 (2012a) and yields the distribution of the fractions of open water, melt ponds, and net sea-ice
2 surface fraction at 0.5 km grid resolution. We average these distributions onto a NSIDC polar-
3 stereographic grid with 12.5 km grid resolution. Together with the above-mentioned fractions
4 the standard deviation of the melt-pond fraction per grid cell and the number of clear-sky 0.5
5 km grid cells contributing to each 12.5 km grid cell are stored in netCDF file format. The
6 number of clear-sky grid cells is taken as a measure of the cloud fraction later. The grid
7 resolution of 12.5 km is chosen in accordance to the 8-day MPF data set derived with the
8 same approach but using 8-day composite MODIS reflectance data for years 2000-2011
9 (Rösel et al., 2012a). We compute the MODIS sea-ice concentration by subtracting the open-
10 water fraction from 100%; note that the MODIS sea-ice concentration includes the sea ice
11 covered by melt ponds while the net sea-ice surface fraction does not. Open-water fraction,
12 melt-pond fraction, and net sea-ice surface fraction add to 100%. For the comparison with the
13 microwave brightness temperatures (sub-section 2.2) and sea-ice concentrations derived from
14 these (sub-section 2.3) we average the MODIS sea-ice parameter data set to 100 km x 100 km
15 grid resolution. In addition, in order to mitigate the influence by variations in the actual sea-
16 ice concentration on our results, we only use grid cells with MODIS sea-ice concentration >
17 90% unless stated otherwise. Throughout the paper we use the term “ice-surface fraction” for
18 net sea-ice surface fraction.

19

20 **2.1.2 Quality assessment of the MODIS sea-ice parameters**

21 The quality of MODIS reflectance measurements carried out at high latitudes may be
22 degraded from high sun zenith angles, long pathways through the atmosphere, cloud shadows,
23 and, in addition, shadows caused by ridges in the sea-ice cover. We use only reflectance
24 values with the highest quality score. This ensures that cloudy pixels and pixels with cloud
25 shadows, pixels with sun zenith angles > 85° and pixels with sensor viewing angles > 60°,
26 plus pixels complying with four additional flag criteria are not used.

27 Mäkynen et al. (2014) hypothesized that our daily MODIS melt-pond fractions are positively
28 biased by about 5-10 % during early melt. In-situ observations carried out north of Greenland
29 revealed a melt-pond fraction of 0% and a sea-ice concentration of 100 % during the first two
30 weeks of June 2009 (Mäkynen et al., 2014). Melt onset dates given in Perovich et al. (2014)
31 support this observation. In order to confirm this notion, we derived histograms of the
32 MODIS melt-pond fraction and the MODIS sea-ice concentration using the data with 12.5 km

1 grid resolution for latitudes north of 83°N for all days before June 7, 9, 11, and 13,
2 respectively (Figure 2). MODIS melt-pond fractions peak at 8%. There are no grid cells with
3 a melt-pond fraction below 4 %. The MODIS sea-ice concentration peaks at 98 % without any
4 grid cell with values > 98%, suggesting a bias of 2%. We can also confirm the magnitudes of
5 the above-mentioned biases from version 01 of the 8-day MODIS melt-pond fraction product
6 (Kern et al., 2015) and conclude the presence of a systematic bias. Therefore we apply a bias
7 correction and subtract 8% from the melt-pond fractions and add 2% to MODIS sea-ice
8 concentrations. A similar correction (minus 8% and plus 3%) was applied to melt-pond
9 fraction and sea-ice concentration of version 01 of the 8-day MODIS melt-pond fraction
10 product (Rösel et al., 2012a; DOI:[10.1594/WDCC/MODIS Arctic MPF](https://doi.org/10.1594/WDCC/MODIS_Arctic_MPF)) yielding version 02:
11 DOI:[10.1594/WDCC/MODIS Arctic MPF V02](https://doi.org/10.1594/WDCC/MODIS_Arctic_MPF_V02)). For the daily product used here, we set the few
12 negative melt-pond fractions resulting from the bias correction to zero.

13 Even though a state-of-the-art cloud masking scheme has been applied to the MODIS
14 reflectance data before the MODIS sea-ice parameter retrieval (Rösel et al., 2012a), there is
15 still a substantial number of misclassified grid cells. It has been demonstrated that even with a
16 multi-channel instrument such as MODIS, cloud classification is a challenge over bright
17 surfaces such as sea ice or snow (Chan and Comiso, 2013; Karlsson and Dybbroe, 2010). In
18 order to mitigate the influence from misclassifications due to residual clouds, we only use 100
19 km grid cells with a cloud cover < 5%. About 15 500 grid cells remain for the analysis. We
20 note that for MODIS collection 6 data (we use collection 5) a further improvement of cloud
21 cover properties in the high latitudes is not foreseen (King et al., 2013; Baum et al., 2012) We
22 find that by changing the cloud-cover threshold to 2% or to 10% (not shown), the number of
23 co-located grid cells is changing but the results shown in Section 3 do not. We estimate the
24 average uncertainty in the melt-pond fraction, net sea-ice surface fraction and MODIS sea-ice
25 concentration due to cloud-induced misclassifications to ~ 5%.

26 More important is the potential misclassification of one of the surface types. The reflectance
27 values used are fixed for the entire summer season and do not take into account the variability
28 in the spectral properties of the melt ponds or the non-ponded sea ice. These spectral
29 properties change as a function of ice type and melt-season duration. The spectral properties
30 of melt ponds are likely to approach those of leads and openings as melt season progresses.
31 This could result in an over-estimation of the melt-pond fraction relative to the open-water
32 fraction or vice versa, because the spectral space between sea ice and water is larger than

1 between melt ponds and open water (leads). Such a misclassification would have, however,
2 no implications for the net sea-ice surface fraction. It would affect only the melt pond or the
3 open-water fraction.

4 Rösler et al. (2012a) report RMSD values between MODIS melt-pond fraction and
5 independent melt-pond fraction observations of 4% to 11%. We compare the MODIS sea-ice
6 concentration with visual ship-based sea-ice concentration observations from seven ship
7 expeditions into the Arctic Ocean and obtain an average RMSD of $(10.3 \pm 3.3)\%$ (range:
8 6.0% to 15.2%). A comparison of our daily MODIS melt-pond fraction data set with
9 contemporary daily melt-pond fraction estimates based on Envisat MERIS data derived with
10 the approach of Istomina et al (2015a) revealed a consistent agreement (Istomina, Institute of
11 Environmental Physics, University of Bremen, personal communication, May 2016). Based
12 on these results we are quite confident, that the average uncertainty of the melt-pond fraction
13 is better than 10% and that the MODIS ice-surface fraction is as accurate as $\sim 5\%$.

14

15 **2.2 Satellite microwave brightness temperatures**

16 We use brightness temperatures measured by the Advanced Microwave Scanning Radiometer
17 aboard the Earth Observation Satellite (EOS) TERRA: AMSR-E. The AMSR-E data used are
18 from the 6.9 GHz, 10.7 GHz, 18.7 GHz, 36.5 GHz, and 89.0 GHz channels, which we
19 abbreviate with 6, 10, 19, 37, and 89 GHz henceforth. We take the AMSR-E swath data from
20 the AMSR-E/Aqua L2A Global Swath Spatially-Resampled Brightness Temperatures data
21 set, version 2: http://nsidc.org/data/docs/daac/ae_l2a_tbs.gd.html, (Ashcroft and Wentz,
22 2013). We resample the brightness temperatures of all channels to the resolution of the 6 GHz
23 channel, which has a 3-dB footprint of 43 km x 75 km, and co-locate these to the MODIS sea-
24 ice parameters provided at 100 km grid resolution (sub-section 2.1). We include data from all
25 AMSR-E passes of the same day as the MODIS data. Only data with footprints which center I
26 located within 5 km of the center of a MODIS sea-ice parameter grid cell are used. AMSR-E
27 sampling is approximately every 10 kilometers so this gives us approximately 1 data point
28 from each AMSR-E pass.

29

30 **2.3 Sea-ice concentration algorithms**

31 We compute sea-ice concentrations from this set of co-located AMSR-E brightness
32 temperatures (sub-section 2.2) using eight selected sea-ice concentration retrieval algorithms

1 investigated in the European Space Agency Climate Change Initiative – Sea Ice (SICCI)
2 project. The full suite of SIC algorithms used in the SICCI project is documented in the
3 SICCI project reports: PVASR (Ivanova et al., 2013) and ATBD (Ivanova et al., 2014), where
4 also the open-water and sea-ice tie points can be found. These represent winter conditions.
5 The motivation for this is two-fold. One is our wish to inter-compare the eight algorithms
6 independently of individual tie points being specifically selected in the original algorithms.
7 We want to use *one* universal set of tie points (see also Ivanova et al., 2015). This implies the
8 second reason why we use winter tie points in the present study. For the derivation of the sea-
9 ice tie points Ivanova et al. (2015) used high ice concentration areas of convergent ice motion
10 during winter. This ensures that i) the areas from which tie points are retrieved are large
11 enough and ii) the areas have indeed 100% sea-ice concentration. Such an approach does not
12 work under summer conditions because openings / leads in the ice cover do not freeze over.
13 In the present study we focus on a selected number of different (representative) types of
14 algorithms (Ivanova et al., 2015) and do not include algorithms where a methodology is
15 duplicated. The selected algorithms are summarized in Table 4.

16 We categorize the algorithms into four types based on the way brightness temperatures are
17 used: 1) algorithms based on one polarization and one frequency (e.g. One_channel 6H); 2)
18 algorithms based on different frequencies but the same polarization such as the frequency
19 mode of the Comiso Bootstrap algorithm (Bootstrap_f); 3) algorithms based on different
20 polarizations but the same frequency such as the polarization mode of the Comiso Bootstrap
21 algorithm (Bootstrap_p); 4) algorithms based on at least two frequencies and/or polarizations
22 like the NASA-Team algorithm (NASA_Team).

23 A fifth type of algorithms are the so-called hybrid algorithms. These combine two or more of
24 the above-mentioned types of algorithms such like the Eumetsat OSI-SAF algorithm
25 (Eastwood et al., 2012) or SICCI (Ivanova et al., 2015) which combine Bristol and
26 Bootstrap_f, and the Arctic version of the Comiso Bootstrap algorithm (Comiso et al., 1997;
27 Comiso 2009), which combines Bootstrap_f and Bootstrap_p. For the high sea-ice
28 concentrations we focus on in this paper, these two hybrid algorithms are almost identical to
29 the algorithm, which is employed at high sea-ice concentrations, that is Bristol in case of the
30 OSI-SAF and SICCI algorithms and Bootstrap_p in case of the Comiso Bootstrap algorithm.
31 Therefore we do not show the analysis for the hybrid algorithms in this paper.

32

2.4 Sea-ice age data set

Brightness temperature changes over Arctic sea ice are different for first-year ice (FYI) and multiyear ice (MYI) (Eppler et al., 1992). In order to separate these two sea-ice types we use the Arctic sea-ice age data set (Tschudi et al., 2016). This data set is available with weekly temporal resolution, has a grid resolution of 12.5 km x 12.5 km and is based on sea-ice drift trajectory analysis (Tschudi et al., 2010; Fowler et al., 2003). We prefer this data set over other approaches because the latter are usually limited to the winter period (e.g. Comiso, 2012; Swan and Long, 2012). We co-locate the sea-ice age data set with the MODIS sea-ice parameter data set as follows. For each MODIS data set grid cell we first find the sea-ice age grid cell which center has the smallest distance to the center of the MODIS data set grid cell. Secondly, we select a 7 x 7 grid cell array around that first co-located grid cell from the sea-ice age data set. Subsequently, we count the numbers with which a certain sea-ice age occurs within the co-located 7x7 grid cell array and divide by the total number (for every ice age) of counts. We assign the ice type FYI to the respective MODIS data-set grid cell only if more than 90% of the counts indicate a sea-ice age of 1 year. We correspondingly assign the ice type MYI only if more than 90% of the counts indicate a sea-ice age of 3 years or older. All other grid cells are kept without any classification into an ice type. In our co-located data set, FYI is assigned to MODIS data set grid cells in the northern Chukchi Seas and parts of the central Arctic Ocean as well as north of Franz-Josef Land (Figure 1 a). Multi-year ice is assigned to MODIS data set grid cells north of the Canadian Arctic Archipelago (Figure 1 b). The latter region is also the area where the largest number of co-locations is found whereas only few co-locations are found in the northern Chukchi Sea (Figure 1 c).

3.1 MODIS sea-ice parameters

We show the temporal development of the daily sea-ice parameters obtained with MODIS (subsection 2.1) for June to August 2009 in Figure 3. These include MODIS sea-ice concentration, the net sea-ice surface fraction, the net surface-water fraction, which is the open-water fraction plus the melt-pond fraction, and the melt-pond fraction for each day and each co-located grid cell. No further averaging is applied and we show all grid cells regardless of ice type. Gaps in the time series and the varying number of data points are caused by daily variations in cloud cover and the decrease in sea-ice cover from June to August. Only grid

1 cells with MODIS sea-ice concentration $> 90\%$ are shown; the number of grid cells fulfilling
2 this criterion is decreasing with progressing melt season.

3 During the first 2-3 weeks the MODIS melt-pond fraction in our data set remains near zero.
4 Then the melt-pond fraction starts to increase, first slowly: days 20-30 (5th and 6th pentad of
5 June), then rapidly: days 30-45 (1st to 3rd pentad of July). After a short plateau where melt-
6 pond fractions remain near 35% it first declines rapidly to about 20% at days 55-60 (last
7 pentad of July) and then more slowly to about 15% until the end of our study period (Aug.
8 31). Throughout June, MODIS sea-ice concentrations are close to 100% (until day 30), and
9 then there is more variability around 90-95% after day 55. Net total water fraction and net
10 sea-ice surface fraction, are linked to the previous two parameters and add up to 100%.

11 **3.2 AMSR-E sea-ice concentration compared to MODIS sea-ice** 12 **concentration**

13 We first compare sea-ice concentrations derived with the algorithms listed in Table 4 from
14 AMSR-E brightness temperatures (sub-sections 2.2 and 2.3) with MODIS sea-ice
15 concentrations (sub-section 2.1) with the aim to illustrate how summer-time AMSR-E sea-ice
16 concentrations compare to an independent sea-ice concentration estimate. We include all data
17 with MODIS sea-ice concentrations $> 20\%$. We find different agreement between AMSR-E
18 and MODIS sea-ice concentrations for the different algorithms for June (Table 5), July
19 (Figure 4, Table 6) and August (Table 7) of the year 2009. Common to all algorithms is a
20 cluster of data, which is more or less centered at an AMSR-E sea-ice concentration of 100%.
21 Slopes of a linear regression forced through the point (0,0) range from 0.90 for Bootstrap_p
22 (Figure 4 e) to 1.12 for Bootstrap_f (Figure 4 b). Values of the root mean square difference
23 (RMSD) between AMSR-E and MODIS sea-ice concentrations vary between 7.4 % for NT2
24 (Figure 4 f) and 18.1 % for Bootstrap_f. Only few values of MODIS sea-ice concentrations $<$
25 80% exist. For these, AMSR-E sea-ice concentrations are generally biased low by between 10
26 and 20% - except for the NT2-algorithm (Figure 4 f). The ASI and NT2 algorithms cut off
27 sea-ice concentrations once they exceed 103% and 100% ice concentration, respectively. We
28 exclude these two algorithms therefore out of the following quality ranking.

29 We take the slope (the closer to 1 the better), the correlation (the higher the better) and the
30 RMSD (the lower the better) as a quality measure and find the NASA-Team algorithm to
31 outperform all other algorithms listed in Table 4 for June (Table 5) – no matter whether we
32 use all grid cells or only FYI or MYI grid-cells (see sub-section 2.4). For July (Table 6), the

1 NASA-Team algorithm is as good as the Near90_lin algorithm. For August (Table 7), best
2 slopes are obtained for the Bootstrap_p algorithm while lowest RMSD values are obtained for
3 the NASA-Team algorithm. Note that the number of FYI grid cells is extremely low for
4 August and that the numbers given in Table 7 for FYI should not be over-interpreted.
5 The average correlation, computed from six algorithms, decreases from June: 0.72 ± 0.07 over
6 0.53 ± 0.18 in July to 0.42 ± 0.10 in August. We believe this can partly be attributed to the
7 known limitations of AMSR-E and other passive microwave sea-ice concentration retrieval
8 algorithms during melting conditions due to varying snow properties and due to melt ponds. It
9 is difficult to quantify the sensitivity of such algorithms to snow-property variations, because
10 their magnitude and spatiotemporal distribution is unknown. In contrast, it should be possible
11 to quantify the sensitivity of such algorithms to melt ponds, because these should theoretically
12 be detected as open water. Consequently, such algorithms should provide an open-water
13 fraction which is the sum of the fractions of leads and openings between the ice floes and of
14 the melt ponds on the sea ice. In order to isolate the influence of the melt ponds one needs to
15 investigate only the high ice concentration areas. The MODIS sea-ice parameter data set (sub-
16 section 2.1), which we use, is ideal for this purpose, because it provides the open-water
17 fraction (in leads and openings), the melt-pond fraction (on sea ice) and the net sea-ice surface
18 fraction. By limiting our investigation to MODIS sea-ice concentrations $> 90\%$ we can take
19 the MODIS ice-surface fraction as an inverse measure of the melt-pond fraction.

20 **3.3 AMSR-E sea-ice concentration compared to MODIS ice-surface fraction**

21 We compare AMSR-E sea-ice concentration (sub-section 3.2) with the MODIS ice-surface
22 fraction (sub-section 2.1) for grid cells with MODIS sea-ice concentration $> 90\%$. For the
23 range of observed MODIS ice-surface fractions between about 50 and 100%, we find quite
24 different ranges of AMSR-E sea-ice concentration (Figure 5). For the Bootstrap_f and 6H
25 algorithm, AMSR-E sea-ice concentrations range between 80 and 150% and 75 and 125%,
26 respectively, and suggest a relatively well-defined linear relationship (Figure 5 a,b). For July,
27 we find a slope between AMSR-E sea-ice concentration and MODIS ice-surface fraction of
28 1.44 and 1.34, respectively. The respective correlation coefficients are 0.855 and 0.820. For
29 the Bootstrap_p and NASA_Team algorithm, AMSR-E sea-ice concentrations tend to cluster
30 in a point cloud with a shallower slope and a less well defined linear relationship (Figure 5
31 c,e). For July, the corresponding slopes are 1.14 and 1.23, respectively, and the respective
32 correlation coefficients are 0.428 and 0.666. AMSR-E sea-ice concentrations derived with the
33 ASI and the NT2 algorithm stay within 75 and 100% and within 85 and 100%, respectively

1 (Figure 5 d,f); the small range in AMSR-E sea-ice concentrations of these to algorithm can
2 clearly be attributed to the cut off mentioned in the sub-section 3.2.

3 We obtain slope, correlation coefficient, and RMSD values of all eight algorithms (see Table
4 4) separately for all grid cells and only the FYI and MYI grid cells (see sub-section 2.4) and
5 summarize these in Tables 8 to 10 for June, July, and August. For August we exclude all
6 values obtained for FYI grid cells because of their low count of 44 (Table 10). We find an
7 increase in the slopes from June to July for all algorithms, which is followed for July to
8 August by a decrease for 6H, Bootstrap_f and Bristol algorithms but a further increase for
9 Bootstrap_p and Near90_lin algorithms. Correlations between AMSR-E sea-ice
10 concentrations and MODIS ice-surface fractions are below 0.4 in June (Table 8) –
11 independent of using all, FYI, or MYI grid cells. In contrast, for July (Table 9) we obtain
12 correlations > 0.8 for 6H, Bootstrap_f, and Bristol algorithms – together with the largest
13 slopes. These suggest a considerable sensitivity of these algorithms to the melt-pond fraction.
14 This does also apply to MYI grid cells. For July, the lowest correlation of 0.43 is obtained for
15 the Bootstrap_p algorithm – together with the smallest slope (Table 9). This suggests the
16 weakest sensitivity to the melt-pond fraction for the investigated algorithms.

17 We carried out the same inter-comparison using a MODIS sea-ice concentration threshold of
18 98% (not shown) instead of 90%. By using 98%, no results can be obtained for August
19 because of too few valid data. For June and July slopes remain similar to those in Tables 8
20 and 9. For June, correlations are considerably smaller compared to using 90%. Correlations
21 are a bit higher for July. Despite this better correlation in July, the peak melting period (see
22 Figure 3), we decided to keep the 90% threshold to ensure a large enough number of data
23 points. The results of the previous paragraph remain the same for 90% and 98% MODIS sea-
24 ice concentration threshold.

25 We conclude: For one type of algorithms, AMSR-E sea-ice concentration is linearly related to
26 the MODIS ice-surface fraction, as we hypothesized in the introduction, i.e., AMSR-E sea-ice
27 concentrations are sensitive to the melt-pond fraction. These are the 6H, Bootstrap_f, and
28 Bristol algorithms. For the other algorithms investigated, such a linear relationship is
29 increasingly less pronounced in the following, descending order: NASA-Team, Near90_lin,
30 Bootstrap_p.

31

4.1 Sea-ice concentration algorithm parameter space

To explain the different sensitivities to the melt pond fraction (sub-section 3.2), we start with an illustration of the distribution of AMSR-E brightness temperatures and contemporary MODIS ice-surface fraction of July 2009 in the parameter spaces of four of the algorithms (Figure 6). These algorithms are: NASA-Team, ASI or Near90_lin, as both rely on brightness temperatures near 90 GHz, and the two Bootstrap algorithms. Bootstrap_f and Bootstrap_p are the two algorithms with the highest and the lowest sensitivity of AMSR-E sea-ice concentrations to melt-pond fraction, respectively (Figure 5, Tables 8 to 10). The NASA-Team algorithm is among the most used ones and the ASI and Near90_lin algorithm have the advantage of a substantially finer grid resolution thanks to using the near 90 GHz channels. In every parameter space we show the following items:

- I. A winter-time AMSR-E brightness temperature distribution for open water (black dots) and AMSR-E NT2 sea ice concentration $> 90\%$ (white dots). The spread of the black dots results from the weather influence over open water. We refer to these as winter data points or winter brightness temperatures in the following text.
- II. Winter-time open water (white cross) and sea ice (black crosses) tie points obtained from Ivanova et al. (2015) and used to compute the AMSR-E sea-ice concentration (see sub-section 2.3 for an explanation of why we use winter tie points).
- III. Red arrows denote the direction of increasing sea-ice concentration.
- IV. AMSR-E brightness temperatures of our data set, i.e. only for MODIS sea-ice concentration $> 90\%$ for the month of July, color coded with the contemporary MODIS ice-surface fraction. We refer to these as summer data points or summer brightness temperatures in the following text.
- V. A red line connecting FYI and MYI tie points denotes the ice line.

4.1.1 NASA-Team algorithm

For NASA-Team algorithm (Figure 6 a) summer data points from July 2009 are located well within the cloud of winter data points (see I.). The NASA-Team tie-point triangle (Cavalieri et al., 1990) is approximated by the dashed white lines and the red (ice) line (see V.). A considerable number of summer data points are located to the left of the ice line. For these data points, NASA-Team sea-ice concentrations exceed 100% and MODIS ice-surface fractions are between 80 and 100% (see the color scale). To the right of the ice line, summer

1 data points coincide with MODIS ice-surface fractions of ~70% and are supposed to provide
2 NASA-Team sea-ice concentrations between 80 and 100% (compare Figure 5 c).

3

4 **4.1.2 ASI or Near90_lin algorithm**

5 For the ASI or Near90_lin algorithm (Figure 6 b) summer data points from July 2009 are also
6 located well within the cloud of winter data points. A considerable number of the summer
7 data points are located above the ice line (see V.). For these data points, ASI or Near90_lin
8 sea-ice concentrations exceed 100%. Most of the summer data points located below the ice
9 line result in ASI or Near90_lin sea-ice concentrations between 80 and 100%. The associated
10 MODIS ice-surface fractions decrease from ~100% close to the MYI tie point to ~70% when
11 following the summer data points towards the FYI tie point and beyond (see Figure 5 d).

12

13 **4.1.3 Bootstrap_f algorithm**

14 For the Bootstrap_f algorithm (Figure 6 c), a substantial number of summer data points from
15 July 2009 fall outside the winter data-point cloud (see I.). The majority of the summer data
16 points are located above the winter ice line (red: our tie points, black: Comiso et al. (1997)).
17 The location of these data points relative to the open-water tie point, the winter ice lines and
18 the tie points for MYI and FYI suggests, that Bootstrap_f sea-ice concentrations exceed 100%
19 by up to a few ten percent (compare Figure 5 b). The distance between the open-water tie
20 point and the winter ice lines increases from left (MYI tie point) to right (FYI tie point).
21 Similar MODIS ice-surface fractions tend to intersect the winter ice lines. Therefore, the over-
22 estimation of Bootstrap_f sea-ice concentration decreases with decreasing MODIS ice-surface
23 fraction (see Figure 5 b).

24 **4.1.4 Bootstrap_p algorithm**

25 For the Bootstrap_p algorithm (Figure 6 d), only few summer data points from July 2009 are
26 located closely above the winter ice lines (see also sub-section 4.1.3). Consequently,
27 Bootstrap_p sea-ice concentrations do not exceed 110% (compare Figure 5 e). As for the
28 Bootstrap_f algorithm (Figure 6 c) only very few summer data points are located close to the
29 MYI tie point. The majority of those data points which are associated with MODIS ice-
30 surface fractions ~70% are located in a relatively broad band parallel to the winter ice lines
31 close to the FYI tie point. The distance between the open-water tie point and the winter ice
32 lines increases upward along these lines. We therefore observe a wide range of Bootstrap_p

1 sea-ice concentrations between 70 and ~100% at MODIS ice-surface fractions of ~70%
2 (compare Figure 5 e).

3 **4.2 Summer sea-ice tie points for the Bootstrap algorithm**

4 We used open-water and sea-ice tie points representative of winter conditions (sub-section
5 2.3). We are not aware of summer sea-ice tie points for the ASI or Near90_lin and the NASA-
6 Team algorithms, but they do exist for the Bootstrap algorithm. The solid cyan line in Figure
7 6 c) denotes the summer sea-ice tie point for the Bootstrap_f algorithm taken from Comiso et
8 al. (1997). For the Bootstrap_p algorithm (Figure 6 d), the solid and dashed cyan lines denote
9 the summer sea-ice tie points for the periods July 1-18 and July 19 to August 4, respectively.
10 For the period after August 4, the summer ice line coincides with the winter ice line (black
11 line in Figure 6 d).

12 We use MODIS ice-surface fractions of the period June 20 to July 5 to derive summer tie
13 points from our summer brightness temperatures. We select only data of MODIS ice-surface
14 fractions $> 97.8\%$ and of vertically polarized 37 GHz brightness temperatures > 250 K. We
15 did not discriminate between different ice types. We compute summer sea-ice tie points
16 (Table 11) at 19, 37 and 89 GHz and from these also derive values of the normalized
17 brightness-temperature polarization difference (PR). These summer sea-ice tie points are also
18 added to Figure 6 c) and d) as cyan crosses.

19 The potential impact of using summer instead of winter sea-ice tie points will be discussed in
20 the following sub-section.

21 **4.3 Temporal evolution**

22 During the melting season, changes in the snow and sea-ice microphysical properties, the
23 associated variations in AMSR-E brightness temperatures, and the retrieved AMSR-E sea-ice
24 concentrations can occur within a few days. It is likely that Figures 4 to 6 do blur such
25 temporal variations which, we think, need to be discussed to understand the observed
26 differences in the sensitivity of the AMSR-E sea-ice concentration algorithms to the melt-
27 pond fraction. Therefore we sub-divide the MODIS and AMSR-E data sets used into pentads
28 (5-day periods) and discuss the temporal evolution for the four algorithms shown in Figure 6.

29 **4.3.1 NASA-Team algorithm**

30 For the NASA-Team algorithm, 1st pentad (June 1-5, Figure 7 a), most summer data points
31 are located at $PR_{19} = \sim 0.03$ (compare Table 11) GR3719 between -0.05 and -0.01. MODIS
32 ice-surface fractions are ~100%. About 20% of the data points belong to the MYI class while

1 only 7 data points belong to the FYI class (see subsection 2.4). NASA-Team sea-ice
2 concentration and MODIS ice-surface fraction agree well with each other by means of slope
3 and correlation coefficient. Later, summer data points cover a larger PR19 range: 0.02 to 0.08,
4 and a larger GR3719 range: 0.0 to -0.09 (June 16-20, Figure 7 b) and: 0.0 to -0.12 (July 1-5,
5 6-10, Figure 7 c,d). We explain the larger PR19 range by an increase in snow density (Table
6 2) and snow wetness (Table 1). We explain the expansion of GR3719 towards more negative
7 values with an increase in the surface layer snow grain size (Table 3). Figures 7 c, d) coincide
8 with the onset of widespread melt-pond formation (see Figure 3, days 30 to 40). MODIS ice-
9 surface fractions are still mostly $> 85\%$ in Figure 7 b), range between $\sim 100\%$ and $\sim 70\%$ in
10 Figure 7 c) and decrease to between $\sim 90\%$ and 60% in Figure 7 d). With further melt
11 progress, the PR19-GR3719 cloud shrinks to GR3719 values of $+0.01$ to -0.06 on July 21-25
12 (Figure 6 f). At this stage MODIS ice-surface fractions are between 60% and 80% .

13 NASA-Team sea-ice concentrations exceed 100% on June 16-20 and especially July 1-5
14 (Figures 7 b,c) with values up to 120% . We find only few values $> 100\%$ for July 21-25,
15 shortly after peak melt (Figure 7 f). After the good agreement between NASA-Team sea-ice
16 concentration and MODIS ice-surface fraction for June 1-5 (Figure 7 a) it breaks down.
17 During July the correlation between NASA-Team sea-ice concentration and MODIS ice-
18 surface fraction increases again, together with the slope, which reaches 1.31 for the pentad
19 July 21-25 (Figure 7 f, compare Table 9). Correlations are ~ 0.5 for most of July which
20 corresponds to an explained variance of about 25% . Therefore, after the onset of wide-spread
21 melt-pond formation beginning of July 2009, NASA-Team sea-ice concentrations and
22 MODIS ice-surface fractions are linearly related to some degree, i.e. the NASA-Team
23 algorithm is sensitive to melt ponds. The relatively low correlation highlights the importance
24 of other processes such as changes in those snow and sea-ice properties, which influence
25 GR3719. These can be snow grain size and wetness (Tables 1 and 3) and, after snow melt,
26 sea-ice salinity, roughness, and density [Eppler et al., 1992; Hallikainen and Winebrenner,
27 1992].

28 4.3.2 ***Bootstrap_f algorithm***

29 For the Bootstrap_f algorithm, 1st pentad (June 1-5, Figure 8 a), most summer data points are
30 associated with MODIS ice-surface fractions $\sim 100\%$, are located beyond the upper border of
31 the winter data points and above the winter ice line (see Figure 6 c). Most Bootstrap_f sea-ice
32 concentrations exceed 100% and the MODIS ice-surface fraction is over-estimated. We can

1 attribute these elevated brightness temperatures to elevated snow wetness (and density) which
2 causes a larger increase in the vertically polarized brightness temperatures at 37 GHz than at
3 19 GHz (Table 1). On June 16-20 (Figure 8 b), almost all summer data points are located
4 above the winter ice line and almost all Bootstrap_f sea-ice concentrations are $> 100\%$;;
5 maxima exceed 140%. The cluster of MODIS ice-surface fractions of $\sim 95\%$ coincides with
6 the cluster of Bootstrap_f sea-ice concentrations centred at 130%. Until July 1-5 (Figure 8 c),
7 the summer data points cloud gradually expands towards lower values. Associated MODIS
8 ice-surface fractions are lowest ($\sim 70\%$) along the bottom of the cloud and highest ($\sim 95\%$) at
9 its left end. We attribute the latter to melt-refreeze cycles causing an increase in snow grain
10 size associated with a smaller brightness-temperature decrease at 19 GHz than at 37 GHz
11 (Table 3). These grid cells at the left end of the cloud are responsible for Bootstrap_f sea ice
12 concentrations of $\sim 140\%$ (compare Figure 8 c) and 6 c). Throughout the remaining three
13 pentads (Figure 8 d) to f), summer data points are shifted towards lower 19 GHz brightness
14 temperatures and are covering a smaller range at both frequencies. We attribute this to
15 complete snow melt. Snow wetness and grain size variations do not influence the brightness
16 temperatures anymore MODIS ice-surface fractions are between 60 and 80% now (Figure 8
17 f), compare Figure 7 f). Maximum Bootstrap_f sea-ice concentrations have decreased to
18 $\sim 120\%$ until July 21-25.

19 The good agreement between Bootstrap_f sea-ice concentration and MODIS ice-surface
20 fraction in the 1st June pentad breaks down during June and re-emerges during July. Between
21 the 3rd July and the 2nd August pentad average correlations are ~ 0.65 explaining $> 40\%$ of the
22 variance. The average slope is 1.45 for these 6 pentads. Therefore, with the onset of wide-
23 spread melt-pond formation also Bootstrap_f sea-ice concentrations and MODIS ice-surface
24 fractions are linearly related to each other, i.e., the Bootstrap_f algorithm is sensitive to melt
25 ponds. This sensitivity is stronger than for the NASA-Team algorithm (sub-section 4.3.1)
26 which could be explained by a smaller influence of the other surface properties mentioned
27 above in the previous sub-section.

28 It is difficult to quantify how this result would change by using summer sea-ice tie points,
29 which we did not use to compute AMSR-E sea-ice concentrations with the two Bootstrap
30 algorithms for the reasons given in sub-section 2.3, but did include in Figure 6 c,d) as cyan
31 lines. The distance between the cyan line and the winter ice lines in proximity to the FYI tie
32 point, measured along the dashed white line, suggests that we would reduce Bootstrap_f sea-

1 ice concentrations by 10% to 15%. Therefore, at this side of the parameter space, Bootstrap_f
2 sea-ice concentrations would be ~100%. However, to the left of the FYI tie point the location
3 of the summer data points (Figure 6c), Figure 8 c,d) suggests, that Bootstrap_f sea-ice
4 concentrations would still be > 120%. Therefore, using summer sea-ice tie points would
5 reduce the slope between Bootstrap_f sea-ice concentrations and MODIS ice-surface fractions
6 but whether the correlations would be similarly high and whether we can exclude unknown
7 non-linear effects cannot be answered in the present paper.

8 4.3.3 *The other algorithms*

9 The temporal evolution of Bootstrap_p sea-ice concentrations in relation to the MODIS ice-
10 surface fraction during June is similar to the Bootstrap_f algorithm (Supplementary Figure S1
11 a,b). One principal difference is the smaller slope we obtain with Bootstrap_p sea-ice
12 concentrations compared to the Bootstrap_f algorithm: ~0.9 vs. ~1.1 for June 1-5 and ~1.1 vs.
13 1.3 for July 1-5; also correlations are smaller. Secondly, we find larger variations of
14 Bootstrap_p sea-ice concentrations around MODIS ice-surface fractions, for example 50% to
15 110% at 90% ice surface fraction. We attribute this to the large and polarization dependent
16 sensitivity of 37 GHz brightness temperatures to variations in snow properties (Tables 1 to 3).
17 In June, any linear relationship to the emerging melt-pond coverage is obscured by this
18 sensitivity. During the first two July pentads, scatter is as high as during most of June.
19 Brightness temperatures associated with MODIS ice-surface fractions of ~90% and ~60% are
20 often located right next to each other in the algorithms' parameter space (Supplementary
21 Figure S1 c,d) which is different to the Bootstrap_f algorithm (Figure 8 c,d). After mid-July, a
22 linear relationship between Bootstrap_p sea-ice concentration and MODIS ice-surface
23 fraction emerges. The average slope is 1.25 and correlations increase from 0.34 (July 16-20)
24 to 0.76 (August 6-10). In summary, also the Bootstrap_p algorithm is sensitive to melt-ponds.
25 The sensitivity is smaller than for the Bootstrap_f algorithm and snow property variations
26 seem to be of larger influence.

27 How does this results change if we use summer sea-ice tie points (Figure 6 d), cyan lines) and
28 sub-section 4.3.2)? The early summer ice line (Figure 6 d), solid cyan line) is steeper than the
29 winter ice lines and intersects these close to the FYI tie point. Therefore, close to the FYI tie
30 point and to the right, all summer data points are below the summer ice line causing
31 Bootstrap_p sea-ice concentrations < 100%. However, to the left of the FYI tie point, summer
32 data points are located above the summer ice line causing Bootstrap_p sea-ice concentrations

1 of up to ~130% close to the MYI tie point. Therefore, for data from 2009, using the early
2 summer sea-ice tie points would not generally provide sea-ice concentrations, which improve
3 the relationship between Bootstrap_p sea-ice concentrations and MODIS ice-surface
4 fractions. The mid-summer ice line (Figure 6 d), dashed cyan line) is located parallel below
5 the winter ice lines. A large fraction of the summer data points is located above the summer
6 ice line causing Bootstrap_p sea-ice concentrations $> 100\%$. For instance, for July 21-25
7 (Supplementary Figure S1 f), about 1/3 of the data points would have a Bootstrap_p sea-ice
8 concentration $> 100\%$; currently: 3 data points. Therefore, for data from 2009, using the mid-
9 summer sea-ice tie points would increase Bootstrap_p sea-ice concentrations increasing the
10 slope between these and MODIS ice-surface fractions, but would not necessarily improve the
11 correlation. Compared to the winter sea-ice tie points, using the early-summer (mid-summer)
12 sea-ice tie points would result in a decreased (enhanced) sensitivity of the Bootstrap_p
13 algorithm to melt ponds.

14 The temporal development of brightness temperatures, sea-ice concentrations and ice-surface
15 fractions obtained with the Near90_lin algorithm (Supplementary Figure S2, Figure 6 b) is
16 comparable to that obtained with the Bootstrap_p algorithm (Supplementary Figure S1). The
17 scatter in summer data points and between Near90_lin sea-ice concentrations and MODIS ice-
18 surface fractions is a little less pronounced and peaks earlier. We attribute the scatter again to
19 snow property variations (Table 1-3). For the smaller electromagnetic wavelength at 89 GHz
20 compared to 37 GHz scattering by coarse-grained snow is more effective than the impact of
21 snow wetness which is evident in the migration of summer data points towards lower values
22 (compare Supplementary Figures S1 b) and S2 b). Maximum Near90_lin sea-ice
23 concentrations of $\sim 120\%$ (Supplementary Figure S2 b) are larger than we expect from
24 comparison with Figure 6 b) and can possibly be attributed to an unaccounted weather
25 influence in the open-water tie point (Figure 6b), white line). After mid-July, correlations
26 increase to their maximum in August 6-10 of 0.81. Slopes are considerably larger than for the
27 Bootstrap_p sea-ice concentration and vary around 1.33. Both, slopes and correlations vary
28 considerably between pentads which we attribute mainly to the larger weather influence at
29 89GHz. Enhanced sensitivity of surface property variations, be it remaining or new snow
30 (Grenfell, 1986) or sea-ice surface wetness changes, at the smaller electromagnetic
31 wavelength at 89 GHz might also contribute. We conclude that the Near90_lin algorithm or
32 other algorithms employing near-90 GHz data such as the ASI algorithm, is sensitive to melt
33 ponds only to some degree. Snow and sea-ice property variations but also the weather

1 influence impact sea-ice concentration retrieval with this type of algorithm as much as / more
2 than obtained for the Bootstrap_p algorithm.

3 With respect to the 6H algorithm and the Bristol algorithm we state, that both algorithms
4 reveal a temporal development of slopes and correlations between AMSR-E sea-ice
5 concentrations and MODIS ice-surface fractions (Supplementary Figures S3 and S4, Tables
6 8-10), which are similar to the Bootstrap_f algorithm. Both algorithms, 6H more than Bristol,
7 are sensitive to melt ponds.

8 4.3.4 **Implications for summer sea-ice concentrations**

9 A MODIS ice-surface fraction value of 60% can in reality be anything between A) 100% sea
10 ice with 40% melt-pond fraction and B) 60% sea ice with 0% melt-pond fraction. Slopes
11 between the AMSR-E sea-ice concentration and the MODIS ice-surface fraction obtained, for
12 example, for the NASA-Team algorithm, of 1.31 (Figure 7 f) would convert 60% MODIS ice-
13 surface fraction into 78% NASA-Team sea-ice concentration. In case B) this would be an
14 *over-estimation* by 18%, while in case A) this would be an *under-estimation* by 22%.

15 We compute the average slope and correlation values of all algorithms, except ASI and NT2,
16 for the 6 pentads July 11-15 to August 6-10 together with resulting over- or under-estimation
17 of case A and case B actual sea-ice concentrations for which we chose ice-surface fractions of
18 60% and 80%. The Bootstrap_f algorithm is most sensitive to melt ponds (highest slope),
19 followed by the Bristol and 6H algorithms (Table 12). The Bootstrap_p algorithm is least
20 sensitive to melt ponds (lowest slope), followed by the NASA-Team algorithm. This
21 sensitivity is most pronounced for the Bristol algorithm (largest correlation), followed by the
22 Bootstrap_f algorithm. The sensitivity is least pronounced for the Near90_lin algorithm
23 (smallest correlation), followed by the Bootstrap_p algorithm. Most pronounced means that
24 snow and sea-ice property variations as well as the weather influence have a comparably
25 small influence. These variations have a larger influence on AMSR-E sea-ice concentrations
26 retrieved with an algorithm with a less pronounced sensitivity to melt ponds. The algorithms
27 with the largest sensitivity to melt-ponds interestingly provide the smallest *under-estimation*
28 of the concentration of melt-pond covered sea ice and the largest *over-estimation* of the
29 concentration of non-ponded sea ice (e.g. the Bootstrap_f and Bristol algorithms, Table 12).
30 The algorithms with the smallest sensitivity to melt ponds provide the largest *under-*

1 *estimation* of the concentration of melt-pond covered sea ice and the smallest *over-estimation*
2 of the concentration of non-ponded sea ice (e.g. Bootstrap_p, Table 12).

3 Using summer sea-ice tie points for the Bootstrap_f algorithm would presumably reduce the
4 mean slope as discussed in sub-section 4.3.2, leading to smaller under- and over-estimation of
5 case A and case B sea-ice concentrations compared to Table 12. Using the mid-summer tie
6 point for the Bootstrap_p algorithm would, in the contrary, presumably increase the mean
7 slope as discussed in section 4.3.3, leading to a larger under- and over-estimation of case A
8 and B sea-ice concentrations compared to Table 12.

9 We investigate the sensitivity to melt ponds of eight sea-ice concentration retrieval algorithms
10 based on satellite microwave brightness temperatures by comparing contemporary daily
11 estimates of sea-ice concentration and melt-pond fraction. We derive gridded daily sea-ice
12 concentrations from Advanced Microwave Scanning Radiometer aboard Earth Observation
13 Satellite (AMSR-E) brightness temperatures of June to August 2009. We use a consistent set
14 of tie points to aid inter-comparison of the algorithms. We derive gridded daily fraction of
15 melt-ponds, open water between ice floes and ice-surface fraction from contemporary
16 Moderate Resolution Spectroradiometer (MODIS) reflectance measurements with a neural
17 network based classification approach. We discuss potential uncertainty sources of this data
18 and conclude that MODIS ice-surface fractions are as accurate as 5-10%. We carry out the
19 comparison of AMSR-E and MODIS data sets at 100 km grid resolution.

20 AMSR-E sea-ice concentrations agree fairly well with MODIS sea-ice concentrations, the
21 sum of the ice-surface fraction and the melt-pond fraction, with slopes of a linear regression
22 between 0.90 and 1.16. However, for some algorithms AMSR-E sea-ice concentrations scatter
23 widely for MODIS sea-ice concentrations larger than 80%. We note that the eventual
24 overestimation of the concentration of the sea ice in between the melt ponds, to produce
25 seemingly ‘correct’ sea-ice concentrations that include the melt ponds, will result in
26 incorrectly overestimating the concentration of sea ice in areas with real open water.

27 We isolate the influence of melt ponds by comparing AMSR-E sea-ice concentrations with
28 MODIS ice-surface fractions only for grid cells with MODIS sea-ice concentrations above
29 90%. By doing so we can use the ice-surface instead of the melt-pond fraction as a measure of
30 the impact of melt ponds and can keep the effect of potential misclassification between the
31 two spectrally close surface types, open water and melt ponds, as small as possible. For most
32 of June, we find a non-linear relation between both data sets. We attribute this to the influence

1 of snow-property variations impacting the microwave brightness temperatures and a still
2 small melt-pond fraction. After June, for one group of algorithms, e.g., the Bristol and
3 Comiso Bootstrap frequency mode (Bootstrap_f) algorithms, sea-ice concentrations are
4 linearly related to MODIS ice-surface fractions. For other algorithms, e.g., Near90GHz and
5 Comiso Bootstrap polarization mode (Bootstrap_p), the linear relationship is weaker and
6 develops later in summer.

7 We take the degree of correlation between AMSR-E sea-ice concentration and MODIS ice-
8 surface fraction as a measure of how sensitive a respective algorithm to the melt ponds is and
9 use the obtained linear regression slope to estimate differences between actual and retrieved
10 sea-ice concentration. All algorithms *under-estimate* the sea-ice concentration of 100% sea
11 ice with an open-water fraction of 40% due to melt ponds (case A) by between 14%
12 (Bootstrap_f) and 26% (Bootstrap_p). The under-estimation reduces to 0% for a melt-pond
13 fraction of ~20%. The concentration of sea ice with a similarly large open-water fraction due
14 to leads and openings between the ice floes (case B) is *over-estimated* by between 14%
15 (Bootstrap_f) and 26% (Bootstrap_p) for 60% sea-ice concentration and by 20% for all
16 algorithms for 80% sea-ice concentration.

17 One next step would be to extend the analysis to more years to confirm the results of our case
18 study with a larger number of data. Currently, at pentad scale, the number of data is too small
19 to use – as an important next step – a higher MODIS sea-ice concentration threshold of 98%
20 instead of 90% to isolate the influence of melt ponds. At monthly scale, e.g. for July, the
21 correlation between AMSR-E sea-ice concentrations and MODIS ice-surface fraction
22 increases from 0.86 to 0.92 (Bootstrap_f), from 0.85 to 0.91 (Bristol), and from 0.67 to 0.76
23 (NASA-Team) while the slopes of the linear regression remain similar.

24 For reasons outlined in the description of the algorithms we use a consistent set of sea-ice tie
25 points derived for winter conditions. By applying published summer sea-ice tie points for the
26 Bootstrap algorithms we find that the slopes of the linear regression would be reduced for
27 Bootstrap_f but not for Bootstrap_p. As a result Bootstrap_f would under-estimate sea-ice
28 concentrations for case A less but over-estimate sea-ice concentrations for case B more.

29 We suggest, that algorithms being more sensitive to melt ponds, could be easier optimized
30 further, because the influence of snow and sea-ice surface property variations, which
31 distribution is unknown, seems to be less pronounced while methods to derive melt-pond
32 fraction, which would be needed for the optimization, have been developed. According to our
33 results, this applies to the Bootstrap_f, Bristol, and Near90_lin algorithms. The Bootstrap_p

1 and NASA-Team algorithms seem to be less suitable for further optimization. While these
2 seem to have the lowest sensitivity to melt ponds and therefore lowest under-estimation for
3 case A, they seem to over-estimate the sea-ice concentration for case B most, among the
4 algorithms investigated.

1 Table 12. Slope of the linear relationship and correlation between AMSR-E sea-ice
2 concentrations and MODIS ice-surface fractions for the six algorithms, which do not cut-off
3 sea-ice concentrations, averaged over the six pentads July 11-15 to August 6-10. For each
4 algorithm, the average value \pm 1 standard deviation (stddev), the range in the slope values and
5 the range in the correlations are given. (EV) denotes the explained variance. Case A60 and
6 A80 denote 100 % sea-ice concentration with 40% and 20% (apparent) open-water fraction
7 due to melt ponds, i.e. 60% and 80% ice-surface fraction, respectively. Case B60 and B80
8 denote 60% and 80% sea-ice concentration in case of 40% and 20% real open-water fraction,
9 i.e. ice-surface fraction = sea-ice concentration. A “*” indicates saturation, i.e. the retrieved
10 AMSR-E sea-ice concentration exceeds 100%. Bold numbers denote the maximum values for
11 mean slope and mean correlation.

Algorithm	6H	Bootstrap_f	Bootstrap_p	Bristol	NASA-Team	Near90_lin
Mean slope \pm 1 stddev	1.36 \pm 0.04	1.44 \pm 0.02	1.24 \pm 0.03	1.36 \pm 0.02	1.29 \pm 0.03	1.33 \pm 0.03
Mean correlation \pm 1 stddev (EV)	0.55 \pm 0.16 (30%)	0.62 \pm 0.10 (38%)	0.49 \pm 0.14 (24%)	0.68 \pm 0.09 (46%)	0.51 \pm 0.10 (26%)	0.46 \pm 0.20 (21%)
Slope range	1.29 to 1.41	1.41 to 1.47	1.21 to 1.29	1.34 to 1.39	1.26 to 1.32	1.29 to 1.38
Correlation	0.33 to 0.78	0.48 to 0.79	0.34 to 0.76	0.58 to 0.82	0.38 to 0.69	0.21 to 0.81
Under-estimation of Case A / over-estimation of Case B sea-ice concentrations by the respective algorithm						
Case A60	-18.4%	-13.6%	-25.6%	-18.4%	-22.6%	-20.2%
Case A80	0.0% *	0.0% *	-0.8%	0.0% *	0.0% *	0.0% *
Case B60	+21.6%	+26.4%	+14.4%	+21.6%	+17.4%	+19.8%
Case B80	+20.0% *	+20.0% *	+19.2%	+20.0% *	+20.0% *	+20.0% *

2 Figure 4. AMSR-E sea-ice concentration computed with 6 of the 8 algorithms listed in Table
 3 2 versus MODIS sea-ice concentration for all grid cells with MODIS sea-ice concentration >
 4 20%, and cloud fraction < 5%. Grey and black symbols denote data of the entire period and
 5 July only, respectively. The black line denotes a linear regression of the sea-ice concentrations
 6 of July forced through (0,0) with the slope as given in the each image. The linear correlation
 7 coefficient and root mean squared difference for sea-ice concentrations of July are denoted by
 8 “Corr.” and “RMSD”. Slope, Corr, and RMSD for June, July (this figure), and August are
 9 summarized in Tables 5 to 7.

2 Figure 5. AMSR-E sea-ice concentration computed with 6 of the 8 algorithms listed in Table
 3 2 versus MODIS ice-surface fraction for all grid cells with MODIS sea-ice concentration >
 4 90%, and cloud fraction < 5%. Grey and black symbols denote data of the entire period and
 5 July only, respectively. The black line denotes a linear regression of the sea-ice concentrations
 6 of July forced through (0,0) with the slope as given in the each image. The linear correlation
 7 coefficient and root mean squared difference for sea-ice concentrations of July are denoted by
 8 “Corr.” and “RMSD”. Slope, Corr, and RMSD for June, July (this figure), and August are
 9 summarized in Tables 8 to 10.

2 Figure 6. Parameter spaces for NASA-Team (a), ASI / Near90_lin (b), Bootstrap_f (c), and
3 Bootstrap_p (d) algorithms. Each image contains AMSR-E brightness-temperature data for
4 the respective space for July 2009, color coded with the contemporary MODIS ice-surface
5 fraction for cloud cover < 5% and MODIS sea-ice concentration > 90%. Black and white dots
6 denote winter (February 10, 2007) Arctic brightness temperatures for 0% and > 90 % NT2
7 sea-ice concentration, respectively. White and black crosses denote open water and sea-ice tie
8 points for winter, respectively (Ivanova et al., 2015). Red arrows direct into sea-ice
9 concentration increase. Red lines connect first-year ice (FYI) and multiyear ice (MYI) tie
10 points and are referred to as ice lines in the text. For white, black, and cyan lines and crosses
11 see text in sub-section 4.2.

2 Figure 7. Background: AMSR-E brightness temperature frequency difference (gradient ratio,
 3 GR) at 37 GHz and 19GHz, vertical polarization, versus AMSR-E brightness temperature
 4 polarization difference (polarization ratio, PR) at 19 GHz, color-coded with the co-located
 5 MODIS ice-surface fraction for 6 selected pentads denoted in the upper left corner of each
 6 image together with the number N of data pairs. For white and black dots see Figure 6.
 7 Foreground: NASA-Team sea-ice concentration versus MODIS ice-surface fraction for the
 8 same pentads together with the linear regression line forced through (0,0). The slope of this
 9 line is given together with the correlation between and the root mean squared difference
 10 (RMSD) of the two data sets in each image.

1

2 Figure 8. Background: Vertically polarized AMSR-E brightness temperature at 19 GHz and
 3 versus at 37 GHz, color-coded with the co-located MODIS ice-surface fraction for the same 6
 4 selected pentads as in Figure 7 denoted in the upper left corner of each image together with
 5 the number N of data pairs. For white and black dots see Figure 6. Foreground: Same as in
 6 Figure 7 but for the Bootstrap_f algorithm.
