8 **Abstract**

9 A new methodology for retrieval of glacier and ice sheet elevations and elevation changes from
10 CryoSat-2 data is presented. Surface elevations and elevation changes determined using this
11 approach show significant improvements over ESA's publically available Cryosat-2 elevation
12 product (L2 Baseline-B), compared to near-coincident airborne laser altimetry from NASA's
13 Operation IceBridge and seasonal height amplitudes from the Ice, Cloud, and Elevation Satellite
14 (ICESat).

15 Applying this methodology to CryoSat-2 data collected in Interferometric Synthetic
16 Aperture mode over the high relief regions of the Greenland ice sheet we find an improvement
17 in the root-mean-square-error (RMSE) of 27% and 40% compared to ESA's L2 product in the
18 derived elevation and elevation changes, respectively. In the interior part of the ice sheet, where
19 CryoSat-2 operates in Low Resolution Mode, we find an improvement in the RMSE of 68% and
20 55% in the derived elevation and elevation changes, respectively. There is also an 86%
21 improvement in the magnitude of the seasonal amplitudes when compared to amplitudes
22 derived from ICESat data. These results indicate that the new methodology provides improved

23 tracking of the snow/ice surface with lower sensitivity to changes in near-surface dielectric
24 properties.

25 To demonstrate the utility of the new processing methodology we produce elevations,
26 elevation changes and total volume changes from Cryosat-2 data for Greenland Ice Sheet
27 during the period Jan-2011 to Jan-2015. We find that the Greenland Ice Sheet decreased in
28 volume at rate of $289 \pm 20 \text{ km}^3 \text{ a}^{-1}$, with high inter-annual variability and spatial heterogeneity in
29 rates of loss. This rate is $65 \text{ km}^3 \text{ a}^{-1}$ more negative than rates determined from ESA's L2
30 product, highlighting the importance of Cryosat-2 processing methodologies.

31 1 - Introduction

32 The European Space Agency (ESA) launched CryoSat-2 in April 2010 tasked with monitoring
33 the changes of the Earth's land and sea ice. CryoSat-2 carries a new type of Doppler/delay
34 radar altimeter (Raney, 1998) referred to as SIRAL (SAR Interferometric Radar Altimeter).
35 SIRAL operates in two different modes over land ice. Over the interior part of the ice sheets it
36 operates as a conventional pulse limited radar system, referred to as the "Low Resolution
37 Mode" (LRM). In more complex high-sloping terrain the system uses a novel second antenna to
38 operate in "Interferometric Synthetic Aperture Radar" (SIN) mode. These new features allow the
39 satellite to monitor changes in complex terrain including ice caps, glaciers and the high relief
40 marginal areas of the ice sheets. Such areas are sensitive to changes in climate and contribute
41 greatly to current rates of sea level rise (e.g., Gardner et al. (2013) and Shepherd et al. (2012)).

42 Ku-band radar altimeters are insensitive to cloud cover providing superior coverage to
43 laser altimeters (e.g., ICESat) but experience significant amounts of volume scattering, which is
44 controlled by the time-evolving dielectric properties of the near-surface snow, firn, and ice
45 (Lacroix et al., 2008; Remy et al., 2012). These effects can have large implications for the
46 determination of mass change over a wide range of both spatial and temporal scales. Changing
47 snow conditions can introduce time-varying biases in the data that, in combination with the radar

48 signals interaction with the surface, introduce large elevation biases (0.5 - 1 m) (Nilsson et al.,
49 2015a). This, combined with other factors such as processing methodology and surface
50 topography, makes it difficult to measure small changes for much of the world's ice covered
51 regions (Arthern et al., 2001; Gray et al., 2015; Nilsson et al., 2015b).

52 The mitigation of these effects in the processing of radar altimetry data is required for
53 improved accuracy of derived temporal and spatial changes in surface elevation of glaciers and
54 ice sheets. Several studies have proposed different approaches to assess these effects and
55 improve the retrieval process of surface elevation and elevation changes from radar altimetry
56 data. These include different approaches to waveform retracking (Davis, 1993, 1997; Gray et
57 al., 2015; Helm et al., 2014) and empirical corrections to the estimated surface elevation
58 changes (Davis and Ferguson, 2004; Flament and Rémy, 2012; Sørensen et al., 2015;
59 Wingham et al., 2006b; Zwally et al., 2005, 2011). Relatively little work has been done to assess
60 methods for improving elevation and elevation changes derived from ESA's CryoSat-2 data
61 (Abulaitijiang et al., 2015; Gray et al., 2013, 2015; Helm et al., 2014).

62 Here we conduct a thorough analysis of CryoSat-2 SIN and LRM waveform retracking
63 and geolocation methodologies to design an optimal processing methodology for CryoSat-2
64 elevation retrieval over both smooth and complex ice-covered terrain. We then analyze several
65 different approaches to determining surface elevation and volume changes from the scattered
66 CryoSat-2 elevation retrievals. The overarching goal of this work is to develop robust and
67 accurate elevation retrieval algorithms that are less sensitive to changes in surface and sub-
68 surface scattering properties.

69 The new processing scheme is applied to estimate elevation and volume changes of the
70 Greenland Ice Sheet for the period January 2011 to January 2015, using two independent
71 methods to characterize the robustness of the results due to methodology. The results are
72 compared to change estimates obtained from the ESA L2 Baseline-B surface elevation product
73 (Bouznjac et al., 2014), high accuracy airborne data from NASA IceBridge airborne topographic

74 mapper and seasonal height amplitudes estimated from Ice, Cloud, and Elevation Satellite
75 (ICESat) data.

76 2 - Surface elevations from CryoSat-2

77 2.1 - Low Resolution Mode (LRM)

78 The LRM mode is used over the interior parts of the ice sheet, which mostly consist of low
79 sloping terrain. Here, SIRAL operates as a conventional pulse limited radar system with a
80 transmission frequency of 13.6 GHz (Ku-band) and has Pulse-Limited Footprint (PLF) radius of
81 approximately 1.5 km and a beam-limited footprint (BLF) radius of approximately 7.5 km over
82 flat terrain (Bouzinac, 2014). The gentle terrain allows for accurate mapping of the surface
83 elevation of the ice sheet down to decimeter-level (Brenner et al., 2007). Within the LRM
84 waveform we define the location of the surface from the leading edge of the waveform, based
85 on a fraction of the maximum amplitude of the received power. This approach is commonly
86 referred to as a threshold retracker. Following Davis et al. (1997) we use 20% threshold to
87 define the location of the surface. Davis et al. (1997) argued that a 20% threshold represents
88 the best compromise between waveforms that are entirely dominated by either volume or
89 surface scattering, making it suitable for obtaining estimates of surface elevation for most parts
90 of the Greenland Ice Sheet.

91 The CryoSat-2 LRM radar waveforms suffer from measurement noise, in the form of
92 speckle noise. Furthermore, over the steeper parts of the LRM-area the range gate tracking-
93 loop can lose track of the surface, producing non-usable waveforms. To remove bad or loss of
94 track waveforms the radar waveform (20 Hz) is first filtered using a zero-phase low pass filter to
95 reduce speckle noise on a line-by-line basis. The signal-to-noise-ratio (SNR) of the waveform is
96 then estimated and if the $SNR < 0.5$ dB the waveform is rejected. The SNR threshold was

97 empirically chosen to obtain a good trade-off between the quality of the measurements and
98 sampling.

99 Before the waveform can be retracked the first surface return (first major peak) is
100 identified within the range gate window. A copy of the waveform is heavily smoothed to remove
101 small-scale surface roughness signals, keeping the overall surface signal intact. The range gate
102 index of the first peak from the copy is then used to extract the leading edge of the original low
103 pass filtered waveform. Only leading edges with a peak index above 20 are used in the
104 retracking, as peaks before or after that indicate troublesome surface ranging. The extracted
105 leading edge is then oversampled by a factor of 100 (c.f. (Gray et al., 2013; Helm et al., 2014),
106 and the range R between the surface and satellite is determined based on the 20% threshold
107 computed according to Davis et al. (1997). The range is then corrected for several atmospheric
108 and geophysical effects relevant to land ice studies according to Bouzinac (2014). The surface
109 elevation H of the topography, relative to the WGS84 ellipsoid, is estimated as $H = A - R$, where
110 A is the altitude of the satellite.

111 The measured surface return over a sloping surface does not originate from the
112 satellites nadir location, but from the “Point Of Closest Approach” (POCA) to the spacecraft
113 (Brenner et al., 1983). These off-nadir returns can introduce a large range bias to the surface,
114 depending on the magnitude of surface slope, ranging from 0-120 m (Brenner et al., 1983) as
115 the measured surface height is mapped to an erroneous position (i.e. the nadir position). To
116 mitigate the effect of this error we correct the measured range and location to the POCA point
117 using an a-prior DEM, following the approach of Bamber (1994). In contrast to previous studies
118 we account also for the local surface curvature, as Remy et al. (1989) showed that accounting
119 for surface curvature in addition to surface slope significantly improve results. The surface
120 slope, aspect and curvature are estimated from an a priori DEM. The GIMP elevation model
121 (Howat et al., 2014) was used to derive surface parameters for the slope-induced error
122 correction in the LRM mode. The DEM was resampled to 2 km resolution, using bilinear

123 interpolation, prior to parameter estimation, corresponding to the pulse-limited footprint of the
124 LRM mode.

125 2.2 - Interferometric Synthetic Aperture Radar Mode (SIN)

126 The SIN mode is used over the marginal areas of the ice sheets and other smaller glaciated
127 areas. In these areas the SIRAL altimeter operates as a Doppler/Delay radar system (Raney,
128 1998). The Doppler/Delay radar allows for higher along-track resolution compared to
129 conventional altimetry, resulting in 350 m resolution in along track and 1500 m across track. In
130 ordinary SAR operation only the amplitude of the radar echo is measured and the phase content
131 is discarded or ignored. With the inclusion of a second antenna on CryoSat-2, interferometric
132 SAR can also be performed. Difference in the path length between the POCA and the individual
133 antennas introduce a phase shift between the two retrieved signals that can be related to the
134 angle of arrival (look angle). The look angle can in turn be used to resolve the across track
135 (across antenna) location of the echo.

136 Multi-look processing is applied to ESA's L1B waveform product (Bouzinac, 2014) to
137 reduce the noise in the SIN waveform but it is still affected by speckle-noise, as is the case for
138 the LRM waveforms. To mitigate this effect, and to help identify the leading edge of the first
139 return, we apply speckle reduction filtering and leading edge extraction of the SIN waveforms in
140 the same way as for the LRM processing with minor changes due to differences in range gate
141 resolution. In this case, compared to the LRM retracking algorithm, only leading edges with a
142 peak index in the range of 20-350 are used for retracking the radar waveform.

143 The estimated coherence C of the multi-looked waveforms is then filtered in two stages;
144 (i) all coherence measures larger than one is set to zeros (larger than one coherence exists in
145 the L1B product reason unknown). (ii) The coherence array, as a function of range, is filtered
146 using a 2D 5x5 Wiener filter to remove high frequency noise. The filtering of the waveform and

147 the coherence is applied to remove noise in the recreation of the interferogram. This is further
 148 discussed later.

149 The measured differential phase ϕ of the return signal is affected by phase ambiguities;
 150 a sudden shift of 2π in the measured phase. To reduce phase noise and aid the phase, an
 151 unwrapping of the radar interferogram I is performed according to Gray et al. (2013):

$$152 \quad I = P \cdot C \cdot e^{-i\phi} \quad (1)$$

153 The interferogram is then filtered using a wavelet-based de-noising technique, where the real
 154 and imaginary parts of the interferogram are filtered separately. The unwrapping of the
 155 interferogram allows for indirect filtering of the phase, without being affected by the phase-
 156 ambiguities. Phase filtering is an important consideration as it has a direct affect on accuracy of
 157 the position of the ground echo. We selected a bi-orthogonal as the mother wavelet to produce
 158 the wavelet coefficients decomposed into three levels. Soft thresholding was applied to detail
 159 coefficients, using a heuristic threshold rule to remove noise at every level. This was done on a
 160 line-by-line basis. The final filtered differential phase was then recovered by:

$$161 \quad \phi_f = Re\{I_f\} + Im\{I_f\} \quad (2)$$

162 To resolve the phase ambiguities the filtered phase measurements require unwrapping. The
 163 phase unwrapping is done on a line-by-line basis in two directions starting from the center of
 164 gravity of the waveform (Wingham et al., 1986).

165 The return power distribution of a Doppler/Delay radar system shows an important
 166 distinction from those from conventional pulse-limited radar systems. Here, the point
 167 corresponding to the mean surface is not located at the half-power point on the leading edge,
 168 but rather closer to the maximum (Wingham et al., 2006a). Therefore a new retracker has been
 169 developed, closely related to the one used in Gray et al. (2013), to allow for adaptive retracking
 170 of the upper parts of the leading edge of the SAR waveform. The algorithm follows the main
 171 concept of the threshold retracker, developed by Davis, (1997), but instead of a pre-defined

172 threshold it tracks the maximum gradient of the leading edge of the waveform. We refer to this
173 approach as that “Leading-edge Maximum Gradient retracker” (LMG).

174 The surface returns are geolocated using the across track look-angle θ estimated from
175 the differential phase at the retrackig point according to (Wingham et al., 2006a). This, in
176 combination with the viewing geometry, is used to define the location of the surface return on
177 the ground using basic across track interferometric principles. We correct θ for the
178 interferometer surface slope error by applying the look-angle scaling factor estimated in (Galim
179 et al., 2013).

180 The along-track differential phase estimate, interpolated to the retracking point, is
181 affected by phase ambiguities not corrected for during the phase unwrapping procedure. To
182 reduce residual phase ambiguities an a priori DEM (GIMP) is used to extract the DEM surface,
183 resampled to 500 m resolution (corresponding to the along-track sampling), elevations at the
184 nadir and echolocation using bilinear interpolation. Over a sloping surface the surface return
185 should always come from a position upslope from the nadir point. Therefore the following
186 relation must hold where ($H_{echo} > H_{nadir}$) or for a more practical application ($H_{echo} - H_{nadir} > \epsilon$,
187 where ϵ is the uncertainty of the DEM used. If this relation is violated 2π is added or subtracted
188 to the individual along-track phase estimate, depending on the sign.

189 A final step is applied to correct for any lingering phase ambiguities not corrected by the
190 a priori DEM. This step uses the assumption that the along-track phase should follow a
191 consistent pattern over most part of the satellite ground track. Hence, any large discrepancies
192 from the overall pattern of the along-track phase would indicate an ambiguity. The ambiguity is
193 detected by computing the residuals of the along-track phase by removing a smoothed version.
194 If any of the residuals have a magnitude larger than π it is considered ambiguous and thus
195 corrected by adding or subtracting 2π .

196 3 - Surface elevation changes from CryoSat-2

197 3.1 – Surface fit method

198 The surface-fitting method is based on fitting a linear model to the elevations as a function of
 199 time and space inside a search radius of 1 km (e.g., Howat et al., 2008; Moholdt et al., 2010;
 200 Sørensen et al., 2011; Wouters et al., 2015). The linear model consists of a time-invariant
 201 (static) bi-quadratic surface model to account for variable topography inside the search radius
 202 and time-variant part used to extract the temporal change in elevation. The model consists of a
 203 total of 7-parameter whereof six of the parameters (a-coefficients) describe the bi-quadratic
 204 surface modeling function, dh/dt the linear elevation change rate, t time in decimal years, t_0 the
 205 mean time inside the footprint and ε the residuals from the linear regression.

$$206 \quad h(x, y, t) = a_0 + a_1x + a_2y + a_3xy + a_4x^2 + a_5y^2 + \frac{\partial h}{\partial t}(t - t_0) + \varepsilon \quad (3)$$

207 The algorithm estimates the elevation change at every echolocation (or grid-node if desired) in
 208 the data set. In each solution the signal amplitude and phase are also estimated by fitting a
 209 seasonal signal model to the surface-fit elevation residuals, according to:

$$210 \quad \Delta h(t) = s_0 \cos(\omega t) + s_1 \sin(\omega t) + \varepsilon \quad (4)$$

211 where Δh is the elevation residuals estimated from the plan-fit model, $s_{0,1}$ are the model
 212 coefficients and t the time. The amplitude A is then defined as $A = \sqrt{s_0^2 + s_1^2}$ and the phase P as

$$213 \quad P = \tan^{-1} \left(\frac{s_1}{s_0} \right).$$

214 To remove outliers an iterative 3σ -filter is used in the full model solution, i.e. the
 215 topography, trend and seasonal signal are removed, using a maximum of 5-iterations. For each
 216 iteration residuals (full-model) with an absolute value larger than 10 m are removed, as
 217 seasonal changes larger than 10 m are not expected (Moholdt et al., 2010; Qi and Braun,
 218 2013). The data inside the 1 km cap is weighted according to their distance from the estimation
 219 point according to:

220
$$W = \frac{1}{\left(1 + \left[\frac{d}{\rho}\right]^2\right)} \quad (5)$$

221 where W is the estimated weight, d the distance and ρ the correlation or resolution parameter
 222 set to 500 m. The weighting allows the solution to better reflect local signal dynamics at the
 223 prediction point.

224

225 Local elevation time-series are further computed from the elevation residuals and
 226 elevation trend from each solution, according to:

227
$$h(x, y, t) = (t - t_0) \cdot \frac{\partial h}{\partial t} + \varepsilon \quad (6)$$

228 where t is the time epochs inside the search cap, t_0 is the mean time of t , dh/dt is the elevation
 229 change rate and ε is the elevation residual at each time epoch.

230 The elevation changes estimated from the surface-fitting method are then culled to
 231 remove outliers before spatial gridding. Elevation changes with a regression error larger than 15
 232 m a⁻¹ are removed. The resulting surface elevations are binned at 5-km resolution for outlier
 233 editing purposes. For each cell the local spatial trend is modeled as a bilinear surface, and
 234 removed. The residuals are then edited using an iterative 3σ filter until the RMS converges to
 235 2%.

236 3.2 – Crossover method

237 The crossover method is used to derive surface elevation at the intersection point between an
 238 ascending and descending satellite ground track separated in time (Brenner et al., 2007;
 239 Khvorostovsky, 2012; Zwally et al., 1989). The surface elevations and times are then estimated
 240 at the crossover location for each track by linear interpolation of the two closest data points. The
 241 crossover height difference is then estimated by taking the height difference between the two
 242 tracks according to:

243
$$\Delta h = h_2 - h_1 + \varepsilon \quad (7)$$

244 were h_1 and h_2 are the surface heights at the crossover location at time epoch t_1 and t_2 ,
 245 respectively, and E is the random measurement error, including orbital, range and retracking
 246 errors.

247 This approach produces crossover height differences with scattered time-epochs
 248 ranging from 0-4 years. CryoSat-2 has a 369-day repeat orbit configuration with a 30-day sub-
 249 cycle meaning that each crossover location will be revisited every 369 days and surrounding
 250 area every 30 days. This produces annual and sub-annual crossover difference around each
 251 crossover location. This fact is used to produce elevation change rates by incorporating all
 252 multi-temporal crossover difference within a neighborhood of 2.5-km around each crossover
 253 location. The elevation change is then estimated using the same procedure described for the
 254 surface-fit method, except that a bilinear model is used to remove any spatial trends in the
 255 topography of the crossover elevations according to:

256
$$dh(x, y, t) = a_1x + a_2y + \frac{\partial h}{\partial t}(t - t_0) \quad (8)$$

257 where dh is the crossover height difference, $(t-t_0)$ the time difference, a_1 and a_2 the across and
 258 along-track slope and dh/dt the elevation change rate. This produces elevation changes
 259 comparable in time and in spatial coverage with the surface-fit method. The same outlier editing
 260 schemes is applied to the crossover elevation change rates as for the surface-fit method.

261 3.3 - Gridding of sparse elevation and elevation change data

262 The gridding is done in a polar-stereographic projection with a latitude of origin at 70°N, central
 263 longitude of 45°W and origin at the North Pole. The projection is referenced against the WGS-
 264 84 ellipsoid and the grid-resolution. The observations derived from the surface-fit are gridded at
 265 a resolution of 1x1-km, due to the high spatial sampling.

266 The method of Least Squares Collocation (LSC), described in Herzfeld (1992) is used to
 267 grid the observations onto a regular grid. LSC is similar to Kriging and allows for optimal

268 interpolation and merging of data with different accuracies, using their inherent covariance
 269 structure. The LSC-algorithm uses the 25 closest data points in 8-quadrants surrounding the
 270 prediction point to reduce spatial biasing. The prediction equation consists of two terms where
 271 the first term is the actual prediction term and the second term accounts for the non-stationary
 272 part of the data, as described by:

$$\hat{s} = C_{sz}(C_{zz} + N)^{-1}z + \left(1 - \sum (C_{sz}(C_{zz} + N)^{-1})\right)m(z)$$

273 where C_{sz} is the cross-covariance, C_{zz} is the auto-covariance, N the diagonal noise-matrix
 274 consisting of the a priori RMS-error and $m(z)$ is the median value of the observations inside the
 275 search neighborhood.

276 The covariance of the data inside the local neighborhood is modeled as a function of
 277 distance away from the prediction point using a third-order Gauss-Markov model described
 278 below.

$$279 \quad C(r) = C_0 \left(1 + \frac{r}{\alpha} - \frac{r^2}{2\alpha^2}\right) e^{\left(\frac{-r}{\alpha}\right)} \quad (10)$$

280 where r is the separation distance, C_0 the local data variance and α is a scaling factor estimated
 281 from the correlation length.

282 LSC interpolation provides a RMS-error for each prediction point estimated from the
 283 modeled covariance of the data according to:

$$284 \quad C_{\hat{s}} = C_0 - C_{sz}(C_{zz} + N)^{-1}C_{sz}^T \quad (11)$$

285 where the RMSE of the prediction equals to $\sigma_{\hat{s}} = (C_{\hat{s}})^{1/2}$ and where C_{sz}^T is the transposed cross-
 286 covariance matrix.

287 The elevation changes estimated from the surface-fit and crossover methods are
 288 interpolated to a regular grid using their a priori error estimated from the LSC scheme. To avoid
 289 unrealistically small errors, common in the regression errors estimated over flat terrain, a
 290 minimum error threshold is applied. Error values smaller than a specific threshold are set to the
 threshold value. The threshold value is representative of the overall precision of the elevation

291 changes over flat terrain and is set to 0.2 m a^{-1} . The data are then gridded using a 75 km
292 correlation length determined from the comparison of CryoSat-2 elevation to airborne
293 measurements (Section 5).

294 The LSC algorithm is also used to generate a DEM based on the surface elevations
295 generated from the surface-fitting algorithm. The surface elevations generated from the surface-
296 fit were used as input to the gridding-algorithm. The use of surface elevations from the surface-
297 fit provides several advantages compared to the raw observations as they: provide an almost
298 equal number of observations as the raw data, have been screened for gross outliers, have
299 been low-pass filtered using the 1-km search radius, and are all reference to the same time
300 epoch. Further the RMSE error generated from the surface-fit estimated surface height can be
301 used as an a priori error for the LSC gridding procedure.

302 The DEM is generated using the same approach as for the surface elevation changes,
303 as described previously in the section. Before the gridding procedure is applied elevations $H < 0$
304 and $H > 3350 \text{ m}$ are removed from the data set. Further, elevations with a standard error larger
305 than 30 m are also removed. The elevations are binned spatially into a resolution of 1000 m and
306 inside each cell the local surface trend is removed by fitting of a planar surface, and an iterative
307 3σ filter is applied to the residuals to remove outliers.

308 4 - Surface elevations and elevation changes from ICESat

309 To assess basin-scale patterns of elevation change we compare elevation changes from
310 CryoSat-2 data to elevation changes derived from Ice, Cloud, and Elevation Satellite (ICESat)
311 data. Here we use release 33 (GLA06) data collected over the 2003-2009 period. The ICESat
312 surface heights were used to generate surface elevation changes and seasonal parameters
313 according to method M3 in Sørensen et al. (2011). The derived elevation changes were
314 corrected for the G-C offset (Borsa et al., 2014). Valid elevation retrievals were selected

315 according to Nilsson et al. (2015b). The ICESat elevation, seasonal amplitude and phase, are
316 then used for comparison with CryoSat-2 and to build continuous time series using the surface
317 fit method described in Section 3.1. For the purpose of this study no correction for the inter-
318 campaign bias was applied, as this is still an active area of investigation.

319 5 -Validation

320 Elevation and elevation change results were generated for the entire Greenland Ice Sheet using
321 CryoSat-2 data collected between Jan-2011 and Jan-2015 using the methodology presented in
322 (Sections 2-3) (JPL product) and by applying the methods of (Section 3) to ESA's CryoSat-2 L2
323 elevation products (ESA product). Surface elevations and elevation changes were validated
324 against airborne data sets obtained from NASA's Operation Ice-Bridge Airborne Topographic
325 Mapper (ATM), obtained from the "National Snow & Ice Data Center" (NSIDC) in the form of the
326 ILATM2 product. The generated elevation product has a resolution of 80 m, with a 40 m spacing
327 along-track. This mission produces both elevation and elevation changes with reported vertical
328 accuracy of ~10 cm and temporal accuracy in the cm-level (Krabill et al., 2002).

329 The derived surface elevations from CryoSat-2 are differenced against ATM surface
330 elevations within 50 m of each ATM locations. One month of CryoSat-2 data consistent in time
331 with the ATM elevations are used for the validation to avoid biases due to temporal sampling
332 and to obtain sufficient sample size. A total of four years of campaign data are used for the
333 validation of the surface elevations (2011-2014). The residuals are edited using an iterative 3σ
334 filter to remove outliers. The accuracy and precision is estimated as the mean and standard
335 deviation of the differences, respectively. The residual distribution is further binned according to
336 surface slope estimated from the GIMP DEM (Howat et al., 2014) resampled to 500 m. The
337 sensitivity to surface slope (slope error) can be identified in the standard deviation of the binned
338 residuals and can be used to judge the quality of the produced surface elevation and elevation

339 changes, while the binned-average for the elevations can be used to determine radar-signal
340 penetration.

341 Surface elevation change rates estimated from three different time-periods (2012-2014,
342 2011-2013 and 2011-2014) of overlapping ATM observations (Krabill, 2014) are used to validate
343 the surface elevation changes estimated from the CryoSat-2 data. The same validation
344 methodology applied to surface elevations is applied to surface elevation changes, with a few
345 minor modifications. First the search radius is increased to 175 m to make it conform to the ATM
346 elevation change resolution of 250 m, as this search radius encloses the entire ATM grid cell.
347 Secondly the estimated mean and standard deviation are multiplied with the individual time-
348 intervals of the validation data sets to make the errors comparable.

349 For the surface-fit and crossover methods, near-coincident elevation change rates were
350 compared with ATM rates (e.g., April-2011 to April-2014). This provided three validation data
351 sets for the surface-fit method, due to its high spatial coverage. However, only the 2011-2014-
352 validation data set could be used for the crossover method, due to the lower spatial sampling of
353 the crossovers.

354 The overall accuracy and precision for both the surface elevation and elevations
355 changes are then estimated by taking the weighted mean, using the number of observations as
356 weights, for each data set giving an average error for each measurement mode, as seen in
357 Table-2. The weighted average errors for each mode and method have been summarized in
358 Table-1 and Table-2 for both the ESA's and our solutions, where the values for the individual
359 campaigns can be found in the Supplementary material.

360 The estimated surface elevation changes from the two independent methods were
361 validated separately using near-coincident ATM data. In general we find the same magnitude of
362 improvement observed in the surface elevation validation analysis. The statistics of the
363 elevation change validation have been summarized in Table-2 for each method independently
364 for the two modes of instrument operation. We find the lowest RMSE errors for the surface-fit

365 method, followed by the crossover method. This differs from the findings of Moholdt et al. (2010)
366 who found lower intrinsic errors for the crossover method, compared to the surface-fit method
367 when applied to ICESat data. The larger search radius used for our application of the crossover
368 method most likely explains the difference in findings between studies. Further, we find that the
369 surface-fit method provides the largest reduction in RMSE for the JPL product, corresponding to
370 40% and 55% for the SIN and LRM-mode, respectively.

371 The correlation length used to derive the number of un-correlated grid-cells, which is
372 used to estimate the standard error, was determined from a semi-variogram analysis of the
373 elevation change residuals from CryoSat-2 minus ATM using the data from the surface-fit
374 method. The comparison was done for each mode separately for all the individual campaigns
375 and multiplied with the their individual time span. The semi-variogram was then computed from
376 all the time-invariant residuals, to maximize the spatial coverage, for each mode. Analysis of the
377 semi-variogram showed approximate correlation lengths of 100 and 75 km for the SIN and
378 LRM-mode respectively. These correlation lengths are inside the range of the ones found by
379 Sørensen et al. (2011) for their analysis of ICESat data, which was found to be 50-150 km.

380 Although the main goal of this study is not to derive or compare different types of DEM's
381 they do play a critical part in removing the long-wavelength topography in order to derive the
382 monthly time-series of volume change from the DEM-method. To gain insight into the overall
383 quality of our CryoSat-2 derived DEM (referred to as JPL) we compare it to three other DEM's
384 derived from other data sets. Firstly, we compare it to a DEM derived from ESA CryoSat-2 L2
385 data (referred to as ESA) gridded in the same manner as our DEM (Section 3.3). Secondly we
386 compare it to a DEM from Helm et al. (2014), also based on CryoSat-2 data from 2011-2014
387 (referred to as AWI). Thirdly, we compare to a DEM from Howat et al. (2014) (which was used
388 to derive topographical parameters and corrections for the JPL CryoSat-2 data), based on
389 photogrammetry data from 1999-2002 co-registered to ICESat elevation data from 2003-2009
390 (referred to as GIMP).

391 These data sets were then compared to IceBridge ATM elevations, spanning the four
392 different campaigns previously used for validation of the CryoSat-2 elevations. The DEM
393 elevation was estimated at each ATM location, using bilinear interpolation, and the elevation
394 difference computed as (DEM-ATM). No attempt was made to account for differences in DEM
395 and ATM epochs. The estimation of the errors of the DEM was determined in the same way as
396 for the individual CryoSat-2 surface heights. The results of the comparison have been
397 summarized in Table-3, as the weighted average of the different campaigns. The values from
398 each individual campaign can be found in the supplementary material.

399 Analyzing the overall RMSE we find that the AWI produces the lowest RMSE, followed
400 by JPL, ESA and GIMP, due to AWI's lower standard deviation. However, the best accuracy is
401 obtained by the JPL DEM, which shows the lowest elevation bias of all DEM's. The ESA derived
402 DEM shows a slightly better standard deviation than the JPL DEM, which can be explained by
403 higher data density in the marginal areas for the ESA data. The difference in density is due to
404 the SNR rejection criterion applied in our elevation processing. This smoothing can explain the
405 lower standard deviations seen for the AWI product. The GIMP data set showed higher degrees
406 of impulse noise than the other products, explaining the higher observed standard deviation.
407 This impulse noise is attributed to that local elevation change rate, which was not accounted for
408 in the creation of the DEM (Howat et al., 2014). Overall we find that the JPL DEM provides a
409 suitable compromise between resolving of local detail and the minimization of bias. Further,
410 modification to the SNR filtering criteria will likely lead to additional improvements in the DEM.

411 To determine the effect of retracking on the accuracy and precision of the measured
412 surface heights from CryoSat-2 several tests was performed over different parts of Greenland
413 for both modes. Following the approach of Davis (1997) the accuracy (mean) and precision
414 (standard deviation) was computed as a function of leading edge threshold (in percent). This
415 computation was performed using a standard leading-edge threshold retracker, referred from
416 now on as LTH, for both the LRM and SIN mode independently. The validation was performed

417 in the same manner as described in Section 5, where ATM elevations from 2013 was used as
418 the surface reference.

419 For the LRM mode data from April 2013 from the northern parts of Greenland, spanning
420 the region 75-81°N and 54-44°W, was used to calculate height residuals for the different
421 thresholds. This produced approximately 1000 comparison locations, which was used to
422 calculate statistics. The same procedure was performed over Jakobshavn Isbræ, using the
423 same time span, to calculate statistics for the SIN-mode providing roughly 2500 comparison
424 locations.

425 The results of this analysis, summarized in Figure-2, show that for the LRM-mode that
426 the precision (as a function of threshold) follows the same behavior as observed by Davis
427 (1997), with a decrease of precision following increasing retracking threshold. However, the
428 most notable finding was the observed inverse relationship in precision for the SIN-mode
429 compared to LRM. For LTH-algorithm, in the SIN-mode, we observe a clear increase in
430 precision as the retracking threshold increases, seen in Figure-2, stabilizing around 30-40%.
431 Analyzing the accuracy derived from the different thresholds a clear difference in apparent
432 penetration depth of the radar signal can be observed for the two modes. For the SIN-mode,
433 below 40%, a positive bias is observed indicating that retracker produces elevations larger than
434 the corresponding airborne measured heights. For thresholds larger than 40% surface
435 penetration of the signal is observed which are in general closer to the surface compared to the
436 LRM-mode. We attribute this to differences in the near-surface density structure covered by the
437 two modes.

438 In general we conclude that for the LRM-mode that low retracking thresholds (0-30%)
439 reduces the magnitude of the apparent surface penetration bias and provides higher precision
440 compared to higher thresholds. Therefore, a threshold of ~20% of the leading edge is
441 suggested for retracking surface elevations for the LRM-mode, which was also previously
442 suggested by Davis (1997) and Helm et al. (2014). However, for the SIN mode a threshold

443 below 40% is not recommended, as this produces a clear positive elevation bias and poor
444 precision, as seen in Figure-2. Analyzing the difference between the LTH and the adaptive LMG
445 algorithm, used in the SIN-mode, we find that the LMG algorithm produces superior results in
446 precision compared to the standard LTH-algorithm. Comparing the adaptive solution from LMG
447 to the optimum threshold found by the LTH-algorithm, we find a comparable magnitude of the
448 elevation bias and a 32% improvement in precision, with an overall 27% reduction in RMSE,
449 using the LMG-retracker. Studying the results from this comparison between the two-retracker
450 algorithms we recommend the use of the adaptive threshold approach, as it produces an
451 elevation repeatability that exceeds that of the standard threshold retracker and provides a low
452 penetration bias.

453 A case study was also performed to determine the different processing steps affect on
454 the quality of the retrieved observations. For this purpose the Barnes ice cap, on Baffin Island in
455 the Canadian Arctic, was chosen due to its small size, excellent validation coverage and due to
456 that it consist mostly of super-imposed ice (reducing radar signal penetration). The ice cap saw
457 a major IceBridge ATM campaign in 2011 providing a large number of flight tracks (spanning in
458 both North-South and East-West directions) suitable for validating CryoSat-2 data. The result of
459 this case study, which is detailed in supplementary material (i.e. Table-S1) shows that the
460 filtering of the differential phase has the highest impact on the overall accuracy of the
461 observation, reducing the RMSE with 12%, followed by the ambiguity correction. This shows the
462 importance of these steps, as they can have important implications for the overall quality of the
463 retrieved elevations. This especially true in high relief areas where small changes in the look
464 angle, or introduced phase ambiguity, can produce large elevation errors ranging from 0-100 m
465 in elevation (Brenner et al., 1983).

466

467 6 - Error analysis

468 To compute volume change errors for the three methods we divide the error budget into two
 469 main components (1) the observational error (ϵ_{obs}) and the interpolation error (ϵ_{int}).

470 The observational error budget is estimated using the root-mean-square error (RMSE) of the
 471 difference between CryoSat-2 and airborne elevation change differences, as described in
 472 Section 5. The RMSE is estimated separately from the two different modes, with the total
 473 volume change error being computed as the RSS of standard error of the two modes, according
 474 to:

$$475 \quad \epsilon_{vol} = \sqrt{(\epsilon_{lrm} A_{lrm})^2 + (\epsilon_{sin} A_{sin})^2} \quad (12)$$

476 where A_{lrm} and A_{sin} are the corresponding areas covered by each mode. The ϵ_{lrm} and ϵ_{sin} are the
 477 standard errors of the LRM and SIN computed from the airborne validation data sets.

478 The observational elevation change error is estimated from the residual elevation
 479 change differences in Table-2 for the two methods. The RMSE from the LRM/SIN errors are
 480 computed using Gaussian error propagation producing an observational elevation change error
 481 (ϵ_{obs}). For the surface-fit and the crossover method the interpolation error is estimated as the
 482 RMS of the LSC uncertainty grid. The final elevation change error is then estimated by combining
 483 the two error sources using RSS according to:

$$484 \quad \epsilon_{dh/dt} = \sqrt{\left(\frac{\sigma_{obs}}{\sqrt{N}}\right)^2 + \left(\frac{\sigma_{int}}{\sqrt{N}}\right)^2} \quad (13)$$

485 Here, N is the number of uncorrelated grid-cells estimated from empirical semi-variogram
 486 analysis of the CryoSat-2 and airborne elevation change differences, and estimated according
 487 to:

$$N = \frac{A}{\rho_c^2} \quad (14)$$

488 where A is the total area of the Greenland Ice sheet ($\sim 1.7 \times 10^6 \text{ km}^2$) and the correlation length ρ_c
 489 of 75 and 100 km for the LRM and SIN mode respectively.

490 7 – Results

491 The measured surface elevations from the two CryoSat-2 products (JPL vs. ESA) showed large
492 differences in both accuracy and precision of the elevation measurements, as seen in Table-1.
493 The average accuracy and precision for the LRM-mode from the two products showed values of
494 0.00 ± 0.43 m and -1.06 ± 0.89 m for the JPL and ESA products respectively. This corresponds
495 to an average reduction in RMSE of 68% for the JPL product compared to the ESA LRM L2
496 data. Further, our product shows a lower residual slope error (seen in Figure-1c below $\sim 0.5^\circ$)
497 indicating a lower sensitivity to the degradation of performance as the surface slope increases.

498 Surface elevations generated from the SIN-mode showed the same type of improvement
499 as for the LRM-mode. Here, an average accuracy and precision was found to be -0.52 ± 0.58 m
500 and -0.90 ± 1.05 m for the JPL and ESA SIN elevation products respectively. This further
501 corresponds to a reduction in the average RMSE of 27% for the JPL product compared to the
502 ESA product. For the SIN-mode the JPL processing produces a slightly lower residual slope
503 error, compared to the ESA processor (seen in Figure-1c above $\sim 0.5^\circ$)

504 Larger improvements can be observed if separating the RMSE into its mean and
505 standard deviation, corresponding to the accuracy and precision of the measurements. Using
506 these definitions the analysis found that there is a 45% and 52% increase in precision for the
507 SIN and LRM mode respectively, compared to the ESA L2 product, and a 42% and 99%
508 improvement in accuracy for the respective modes.

509 The estimated surface elevation changes generated from the surface-fit method also
510 showed improvement in the estimated accuracy and precision, as seen in Table-2. Here, a
511 overall improvement in RMSE of 55% and 40% in the LRM and SIN mode, respectively, was
512 found when comparing against ESA L2 generated elevation changes from the same method.
513 The average accuracy and precision, compared to ATM generated elevation changes, was
514 found to be 0.11 ± 0.67 m (LRM) and 0.30 ± 0.58 m (SIN) for the JPL derived changes. This

515 compared to 0.25 ± 1.51 m (LRM) and 0.34 ± 1.06 m (SIN) for the ESA derived changes. This
516 corresponds to an increase in elevation change accuracy of 56% and 12% for the LRM and
517 SIN-mode, respectively, for the JPL product compared to ESA L2 elevation changes. The
518 estimated elevation changes also show an increase in precisions for the JPL product of 56%
519 and 45% for the LRM and SIN-mode, respectively, compared to its ESA counterpart.

520 The implementation of the LMG SIN retracking algorithm was found to reduce noise in
521 the retrieved surface elevations compared to conventional threshold retracking. Though roughly
522 comparable in accuracy, the LMG shows overall higher precision over all comparable leading
523 edge thresholds. The adaptive nature of the algorithm provides improved estimates of surface
524 elevation and gives good trade-off between accuracy and precision.

525 The 20% threshold retracker implemented in the LRM-mode was also found to provide
526 improved estimates of surface elevation (both in accuracy and precision) compared to the
527 model-based ESA-L2 retracker. Further, it also showed lower sensitivity to the 2012 melt event,
528 due to the lower threshold used on the leading edge of the waveform.

529 The estimated elevation changes of the Greenland Ice Sheet, excluding the peripheral
530 glaciers, over the period January 2011 to January 2015 show significant differences between
531 products (JPL and ESA) in both spatial patterns and the total magnitude (Figures 3 & 4). The
532 estimated volume change rate from the surface-fit method is -289 ± 20 km³ a⁻¹ for the JPL-
533 product and -224 ± 38 km³ a⁻¹ for the ESA-product with a mean difference of 65 km³ a⁻¹. The
534 surface-fit and crossover-method produced on the order of ~20 million and ~2.5 million usable
535 elevation changes, respectively, providing high spatial sampling. Due to the constraint put into
536 the JPL processor the ESA L2 data produced slightly more surface-fit observations (~10%), as
537 more surface elevations were accepted.

538 The ESA product produces a more positive elevation change pattern, which can be
539 attributed to the 2012 melt event that introduced a large positive bias with a magnitude of ~0.5
540 m (Nilsson et al., 2015). Larger differences in the marginal areas for the surface-fit methods are

541 also observed. These are particularly noticeable in eastern Greenland (near 73.5 degrees in
542 latitude Figure 3) where the ESA data shows marginal areas of rapid thinning that are not visible
543 in the JPL solution. The positive signal detected in the interior of the ESA surface-fit-solution
544 can also be found in the basin time series, correlating well with the timing of the summer of
545 2012 melt event. These results are in agreement with earlier work demonstrating the sensitivity
546 of the ESA retracker to the changes in the volume/surface scattering ratio (Nilsson et al., 2015).

547 The two volume change methods produce consistent results from JPL derived elevation
548 changes, with a difference of around $1 \text{ km}^3 \text{ a}^{-1}$. The spread between volume change methods is
549 larger ($50 \text{ km}^3 \text{ a}^{-1}$) when using ESA L2 data. The larger discrepancy can mostly related to the
550 sensitivity of the various methods to the melt event. The surface-fit method produces the most
551 negative number (least affected by the melt event and the lowest estimated error) and is
552 therefore taken as the most reliable estimate for both the JPL and ESA solution.

553 Comparing the estimated volume change to other studies using CryoSat-2 we find that
554 the JPL product is less negative than that estimated by Helm et al. (2014): $-375 \pm 24 \text{ km}^3 \text{ a}^{-1}$.
555 This difference can be attributed to difference in processing methodology and to the different
556 epoch of the data used by Helm et al. (2014) of January 2011 to January 2014. Using the
557 corresponding epoch the JPL data gives a volume change estimate, based on the surface-fit
558 method, of $-353 \pm 21 \text{ km}^3 \text{ a}^{-1}$, well within the stated uncertainty of Helm et al. (2014).

559 To examine the regional behavior of volume change estimates of the Greenland Ice
560 Sheet, gridded values from the three methods were divided into 8-drainage basins according to
561 Zwally et al. (2012). When analyzing the volume change time-series at the basin scale clear
562 differences can be observed in the annual and inter-annual behaviors (Figure 4). The northern
563 and interior basins (1, 2, 7, 8) all exhibit large differences (Table 4: $0 - 30 \text{ km}^3 \text{ a}^{-1}$) in the
564 estimated volume change rates due to changes in the scattering regime resulting from the 2012
565 melt event. In the majority of the southern basins (4, 5, 6, 7), located in areas with higher

566 precipitation, both products show good agreement in both trends and seasonal amplitude
567 estimated from the surface-fit method.

568 The amplitude of the seasonal signal (Equation 4) estimated from the surface-fit (SF)
569 method show large differences in both magnitude and spatial variability (Figure 5). For the
570 surface-fit method a difference in amplitude of 54% is observed between the ESA and JPL
571 products, corresponding to area-averaged amplitude of 0.17 m for the JPL product and of 0.37 m
572 for ESA product. The comparison with ICESat derived amplitudes from 2003-2009 estimated in
573 (Sasgen et al., 2012) using the same methodology as used here produced an area-averaged
574 amplitude of 0.13 m, which is in good agreement with the JPL derived amplitude. This
575 agreement is also spatially consistent, as seen in (Figure 5), indicating low sensitivity to
576 seasonal changes in scattering regime of the upper snowpack. The observed difference in
577 amplitude bias, taking ICESat as the true surface amplitude while acknowledging that no inter-
578 campaign bias has been applied and the differences in epochs, is 0.03 ± 0.13 m for the JPL
579 product and 0.21 ± 0.27 m for the ESA product. The smallest differences are observed at high
580 altitudes above 2000 m a.s.l., where the three data sets show almost constant amplitude of 0.1
581 m (ICE/JPL) and 0.2 m (ESA), providing a factor of two larger amplitude for the ESA product.
582 Below 2000 m a.s.l., corresponding well to the equilibrium-line-altitude (ELA) of the Greenland
583 Ice Sheet, a rapid increase in amplitude is observed for all products. This is especially true for
584 the ESA product, which increases its magnitude by a factor of two.

585 Analyzing the amplitude patterns on a regional drainage basin level (Figure 5c) we find
586 good agreement between JPL CryoSat-2 and ICESat amplitude with ESA data producing
587 consistently larger amplitudes. Regionally, the highest amplitudes can be observed in the SE of
588 Greenland in basins (3,4,5) and are consistent with regional precipitation patterns that show
589 high average precipitation in these areas (Bales et al., 2009; Ettema et al., 2009).

590 The seasonal phase of the peak in amplitude of the seasonal cycle is shown in (Figures
591 5b and 5c) and shows generally good agreement between the two products, providing the

592 timing of the maximum of the accumulation signal, before the onset of melt, to the months of
593 June/July for both JPL and ESA CryoSat-2 data sets. The ICESat derived seasonal phase
594 shows a higher dependence on elevation where the maximum of the accumulation signal is
595 found in late May below 2000 m and late July/August above 2000 m in elevation. The ICESat
596 discrepancies from the CryoSat-2 data are found in specific basins. Disagreements between the
597 retrieved phase of the peak amplitude from Cryosat-2 and ICESat data are due to differences in
598 temporal sampling as discussed in more detail in Section 8.

599 We used ICESat and CryoSat-2 derived surface heights to generate time series over
600 three regions in Northeast area of Greenland (Zachariæ Isstrøm, Nioghalvfjerdingsfjorden and
601 Storstrømmen glaciers) for comparison purposes These areas have in recent time shown large
602 and rapid changes, which has been noted by, e.g., Khan et al. (2014). The selected areas were
603 defined using hydrological basins derived by Lewis and Smith (2009), seen in (Figure 6), and
604 were further divided into smaller areas around the termini to highlight performance for areas of
605 rapid change. The ICESat and CryoSat-2 surface heights were then used to generate annual
606 time-series from 2003-2015 using (Equation 6) in the surface fit method. The estimated 12 year
607 time series show overall comparable elevation change rates over both time periods, especially
608 in the terminus areas, providing confidence that CryoSat-2 can actually monitor changes in
609 these areas.

610

611

612

613

614

615 8 - Discussion

616 The CryoSat-2 processing methodology presented here is found to produce accurate and
617 precise measurements of ice sheet elevation and elevation change. The main improvements
618 have been introduced in the SIN processor with the inclusion of a new type of land ice retracker
619 (LMG), advanced phase filtering and the inclusion of a phase ambiguity correction scheme. This
620 processing approach decreased the RMSE in the surface height retrieval by approximately 27%
621 (45% and 42% improvement in precision and accuracy). This improvement further propagated
622 into the quality of the estimated elevation changes for the SIN-mode, with the same magnitude
623 of improvement (Table-2). The described SIN-processing also generated surface elevations and
624 elevation changes with lower sensitivity to the local surface slope, indicating a higher degree of
625 accuracy in the geo-location and surface range estimation.

626 The SIN processing methodology further includes a phase filtering and phase ambiguity
627 correction scheme. Visual inspections of a large number of tracks have shown more coherent
628 estimation of the surface locations in our product and further the implementation of the phase-
629 ambiguity correction greatly reduced the number of track offsets. It was also noted that a
630 relatively coarse DEM (~1 km) could be used to resolve phase ambiguities. The detection and
631 correction of phase ambiguities are relatively straightforward and rely mostly on the relative
632 accuracy of the DEM. The implementation of the phase ambiguity correction is particularly
633 important when monitoring smaller ice caps and outlet glaciers, where frequent and large track
634 offsets can bias the estimation of the underlying topography.

635 The new LRM processing methodology focused on optimal retrieval of surface
636 elevations over the interior parts of the ice sheet. Here the choice of retracking threshold has
637 proven to be the critical factor to acquire high quality surface elevations and elevation changes.
638 The choice of 20% leading edge threshold level reduced the sensitivity to changes in the
639 scattering regime for low slope, high elevation areas. The functional-based retracking algorithm

640 used in the ESA LRM processor corresponds roughly to a 50% threshold level (Wingham et al.,
641 2006a), which appears to suffer from a higher sensitivity to changes in the scattering properties
642 (volume scattering) of the near-surface firn, as the range is reference higher up (later in time) on
643 the leading edge of the waveform. This effect can be seen in (Figure 2a), and that the observed
644 negative elevation bias (Table-1) for ESA-LRM (-1.0 m) fit well with the bias for the 50% LRM
645 threshold value shown in Figure 2a. This makes the algorithm more sensitive to annual and sub-
646 annual changes in snow-packs volume/surface scattering ratio, which can produce spurious
647 changes in elevation due to changes in the near surface dielectric properties. This is clearly
648 shown in patterns of ESA product derived elevation changes (Figure 3) where a large elevation
649 bias was introduced by the 2012-melt event (Nilsson et al., 2015a). The 20% threshold is less
650 sensitive to these types of changes (Table 1 & 2) and is in agreement with previous work that
651 has demonstrated that the 20% threshold best represents the mean surface inside the footprint
652 when exposed to a combination of surface and volume scattering (Davis, 1997).

653 Surface elevation changes, derived from multi-temporal radar altimetry observations, are
654 typically corrected for their correlation to changes in the radar waveform shape. This is to
655 reduce the effect of changes in the volume/surface scattering ratio of the ice sheets surface
656 (Davis, 2005; Flament and Rémy, 2012; Wingham et al., 2006b; Zwally et al., 2005). This
657 inherently adds to the complexity of the processing and analysis, introducing new biases and
658 error sources in the estimated parameters. For the processing approach presented here many
659 of these steps can be omitted or reduced, as they are an inherent part of the improved
660 waveform retracking. There have been attempts to remove spurious step-changes in elevation
661 resulting from sudden changes in surface scattering characteristics (caused by the 2012 melt
662 event) apparent in the ESA Baseline-B L2 data through post-processing strategies (Nilsson et
663 al., 2015c), but such approaches spread the bias over a longer period of time making the
664 “jumps” less noticeable in the time series by removing the step-change but introduces longer-

665 timescale bias of equal magnitude as the scattering layer is buried by less reflective snow and
666 low-density firn.

667 The result of the validation procedure shows a larger slope dependent bias in the ESA
668 data, both in the elevation and elevation changes (Figure-1). This is especially true for the
669 surface elevations, which can be seen in the figures of precision and accuracy (Figure 1a and
670 1c), where both figures show clear linear slope for the ESA surface heights. In comparison,
671 estimated elevations from JPL-product show relatively stable statistics over the entire slope
672 range above 0.2° . The validation of the estimated surface elevation changes, seen in (Figure
673 1b) and (Figure 1d), shows the effect of the 2012 melt event on the ESA derived elevation
674 changes below 0.2° . Further, the accuracy of the ESA derived changes show a clear negative
675 trend as function of increased surface slope. The derived precision of the surface elevation
676 change increases dramatically above 0.5° , as more complex topography is measured.

677 The JPL CryoSat-2 processing methodology produces seasonal amplitudes that are in
678 good agreement with those derived from ICESat data, further indicating the processors abilities
679 to track real and physical changes of the ice sheets surface. The current ESA implementation
680 produces noisier estimates of elevation change, as indicated by the larger standard deviations
681 of the residuals in the ESA solutions for the surface-fit and crossover-method. Figure 5 further
682 shows an amplitude bias in the ESA data compared to the corresponding ICESat reference
683 amplitudes. The bias is constant above the Greenland ELA located around 2000 m in altitude
684 but increases linearly as elevations decrease below this. The linear increase in amplitude
685 seems to be connected to the higher and more variable precipitation in the ablation zone where
686 changes in the variable snow cover produces changes in apparent surface height. This is less
687 prominent for the JPL SIN and LRM retracers. The estimated seasonal phase in Figure 5c and
688 5d show that both JPL and ESA CryoSat-2 elevation products can adequately resolve the
689 seasonal maximum of the accumulation signal. Both products provide a timing of the maximum
690 to the month of July over the entire ice sheet, independent of elevation. Assessing the CryoSat-

691 2 derived maximum one does however notice a difference between CryoSat-2 and the
692 reference ICESat dataset. This constitutes roughly a ± 1 month difference depending on the
693 elevation and the location. The cause of this difference can be attributed to the temporal
694 sampling of the ICESat mission. During the mission, due to degraded laser lifespan, data was
695 only collected in campaign mode during the spring and winter times corresponding to roughly
696 two months of measurements for each period. When the CryoSat-2 data was resampled to
697 coincide with the ICESat temporal sampling the same elevation and spatial pattern in the phase
698 of the maximum seasonal amplitude was observed as determined from the ICESat data. No
699 corresponding change in amplitude was observed. To mimic the temporal sampling of ICESat
700 the each year of the CryoSat-2 data was resampled using the total number of unique months in
701 the ICESat campaign record. This as the specific months used in the ICESat sampling changes
702 with different campaigns.

703 The two independent methods used to estimate the volume change of the Greenland Ice
704 Sheet produce consistent volume change estimates. This was especially true for volume
705 changes derived from the JPL elevations, with a discrepancy of less than $1 \text{ km}^3 \text{ a}^{-1}$ between
706 methods. The two methods provided the same estimate of integrated volume change but the
707 use of the surface-fit is recommended as it produces higher spatial sampling compared to the
708 crossover-method and lower errors. The good agreement between the methods further
709 indicates a strong reliability in the estimated volume change rates of the Greenland Ice Sheet
710 over the four-year period. It also shows the ability of CryoSat-2 to capture both small and large-
711 scale spatial patterns in the rugged topography along the coastline and in the interior of
712 Greenland. This is especially true in the major outlet glacier systems (e.g., Zachariæ Isstrøm,
713 Nioghalvfjærdsfjorden and Storstrømmen).

714 Studying the northern parts of the Greenland Ice Sheet we find that CryoSat-2 captures
715 both intricate and complex behavior in the marginal areas of the ice sheet. This is exemplified in
716 the NE regions of Greenland (Figure 6) near Zachariæ Isstrøm, Nioghalvfjærdsfjorden and

717 Storstrømmen, which all show complex and localized patterns of elevation change. Here,
718 Nioghalvfjærdsbrae shows very small changes in elevation during the observational time-span,
719 while Zachariae Isstrøm, its major neighbor shows large negative trends in elevation change.
720 The observed behavior agrees with the observations made in recent studies by Khan et al.
721 (2014) and Mougnot et al. (2015) who document rapid retreat and drawdown of the ice-front
722 position of the two systems beginning in 2012. Storstrømmen outlet glacier system also appears
723 to show signs of rapid thinning at low elevations near the ice-front position while a large positive
724 signal is observed roughly 100 km upstream of the terminus. This pattern has also been
725 observed by Joughin et al., (2010) and Thomas et al., (2009), using airborne altimetry and
726 surface velocity mapping. Rates of elevation change from ICESat and CryoSat-2 data show
727 good agreement in basin-scale trends (Figure 6b,c).

728 The observed volume change rates estimated from this study are within the range of
729 previous studies, ranging from -186 to $-309 \text{ km}^3 \text{ a}^{-1}$ for the time period 2003-2009, summarized
730 by Csatho et al. (2014). A more recent study by Helm et al. (2014: $-375 \pm 24 \text{ km}^3 \text{ a}^{-1}$) agrees
731 within uncertainties when differences in observation periods (2011 – 2014 vs. 2011 - 2015) are
732 taken into account. Assuming no changes in firn air content over respective study periods and
733 an ice density of 917 kg m^{-3} we compare estimated changes with corresponding estimates of
734 mass change our estimated rate of Greenland glacier volume change. An assessment of
735 changes in firn air content is out of the scope of this paper. Velicogna et al. (2014) estimated
736 mass loss using the Gravity Recovery and Climate Experiment satellites (GRACE) over the
737 time-period 2003-2013 provided (converted from mass) a rate of $-305 \pm 63 \text{ km}^3 \text{ a}^{-1}$ for the
738 Greenland which is inclusive of changes in Ice Sheet and peripheral glacier ice mass (-41 ± 8
739 $\text{km}^3 \text{ a}^{-1}$, Gardner et al., 2013). The estimated volume change of $-265 \text{ km}^3 \text{ a}^{-1}$ from Csatho et al.
740 (2014) and the estimated rate of $-305 \text{ km}^3 \text{ a}^{-1}$ from Velicogna et al. (2014) spans our estimated
741 rate of $-289 \text{ km}^3 \text{ a}^{-1}$.

742 9 – Summary and Conclusion

743 We conclude that the use of an adaptive retracker for the SIN-mode, based on the maximum
744 gradient method, and the use of 20% threshold retracker for the LRM-mode provide improved
745 performance to the retracker currently used for the ESA L2 elevation products. It is further
746 important, especially for the SIN-mode, to apply a leading edge discriminator to identify and
747 track the leading edge of the waveform. The functional model currently employed in the ESA
748 processor has, to the author's knowledge, no such discriminator currently implemented. This is
749 important in the SIN-mode, as it often contains multiple surface returns. The single-return model
750 applied in the ESA processor will here have issues fitting a waveform containing multiple
751 surface returns resulting in retrack jitter (Helm et al., 2014).

752 Using the new CryoSat-2 processing methodology for the LRM and SIN-mode we
753 determine the volume change of the Greenland Ice Sheet to be $-289 \pm 20 \text{ km}^3 \text{ a}^{-1}$ during the
754 period January 2011 to January 2015. The validation against airborne ATM surface elevations
755 and elevation changes showed an average improvement in the RMSE of the measured
756 elevations of 68% and 27% for the LRM and SIN mode respectively compared to ESA Baseline-
757 B L2 products. The new methodology also provide improved elevation changes with an
758 reduction in RMSE of 55% and 40% for the LRM and SIN mode respectively, compared to their
759 ESA L2 derived counterparts.

760 The methodology also showed less sensitivity to changes in near-surface scattering
761 properties than equivalent ESA products. The new processing methodology showed little effect
762 of slope-induced errors, providing better performance in the marginal areas of the ice sheets.
763 These improvements to the CryoSat-2 processing mitigate the need for post-processing to
764 correct correlations between changes in surface elevation and changes in the waveform shape
765 (i.e. backscatter and leading edge width etc.) that can introduce biases and add to the
766 complexity of the processing and analysis.

767 The presented CryoSat-2 processing methodology provides a lower intrinsic error in the
768 measured elevation, elevation change and volume change estimates, all of which will facilitate
769 improved understanding of the geophysical process leading to changes in land ice elevation.
770 Given the release of the ESA Baseline-C, which provides improved corrections and processing
771 mainly for the L1B product, further improvements are expected in the near future.
772 The complete set of grids used in this study is available for the public from the main author (J.
773 Nilsson) upon request and are provided in geotiff format.

774 Acknowledgement

775 We are deeply thankful for the guidance of Laurence Gray and support of David Burgess. We
776 also thank Sebastian Bjerregaard Simonsen for very fruitful discussions. Further, we would also
777 thank and acknowledge Frank Paul at the University of Zurich for providing us with polygon-
778 outlines of the Greenland Ice Sheet and to the European Space Agency for providing their
779 CryoSat-2 L1b product. We thank the editor E. Berthier, the reviewer L. Schröder and the
780 anonymous reviewer for their valuable comments, which greatly helped to improve this
781 manuscript. This work was supported by funding from the NASA Cryosphere program. The
782 research was conducted at the Jet Propulsion Laboratory, California Institute of Technology
783 under contract with NASA.

955 Tables:

956 *Table 1: Accuracy (Mean), precision (SD) and the total RMS-error (RMSE) of surface elevation*
 957 *from CryoSat-2 observations compared to IceBridge ATM elevations. Here, the LRM mode*
 958 *represents the interior of the ice sheet and SIN the marginal high relief areas.*

JPL	Mean (m)	SD (m)	RMSE (m)
LRM	0.00	0.43	0.45
SIN	-0.52	0.58	0.82
ESA	Mean (m)	SD (m)	RMSE (m)
LRM	-1.06	0.89	1.40
SIN	-0.90	1.05	1.13

959

960 *Table 2: Accuracy (Mean), precision (SD) and the total RMS-error (RMSE) of surface elevation*
 961 *changes from CryoSat-2 derived from two independent methods [Surface Fit (SF) an the*
 962 *Crossover (XO) method], compared to IceBridge ATM data.*

JPL - LRM	Mean (m)	SD (m)	RMSE (m)
SF	0.11	0.67	0.70
XO	0.24	0.72	0.78
ESA - LRM	Mean (m)	SD (m)	RMSE (m)
SF	0.25	1.51	1.57
XO	0.60	1.02	1.20
JPL - SIN	Mean (m)	SD (m)	RMSE (m)
SF	0.30	0.58	0.66
XO	-0.60	1.26	1.26
ESA - SIN	Mean (m)	SD (m)	RMSE (m)
SF	0.34	1.06	1.11
XO	-0.21	1.44	1.44

963
 964

965 Table 3: Validation of four different DEMs, compared to IceBridge ATM elevation data. Based
 966 on the weighted (number of samples) average of the four different ATM campaigns from 2011 to
 967 2014. Elevation values at each ATM location were estimated by bilinear interpolation for each
 968 DEM product.

DEM	Mean (m)	SD (m)	RMSE (m)
AWI	-1.35	5.95	6.12
GIMP	-1.13	7.22	7.32
JPL	-0.87	6.31	6.39
ESA	-2.83	6.13	6.76

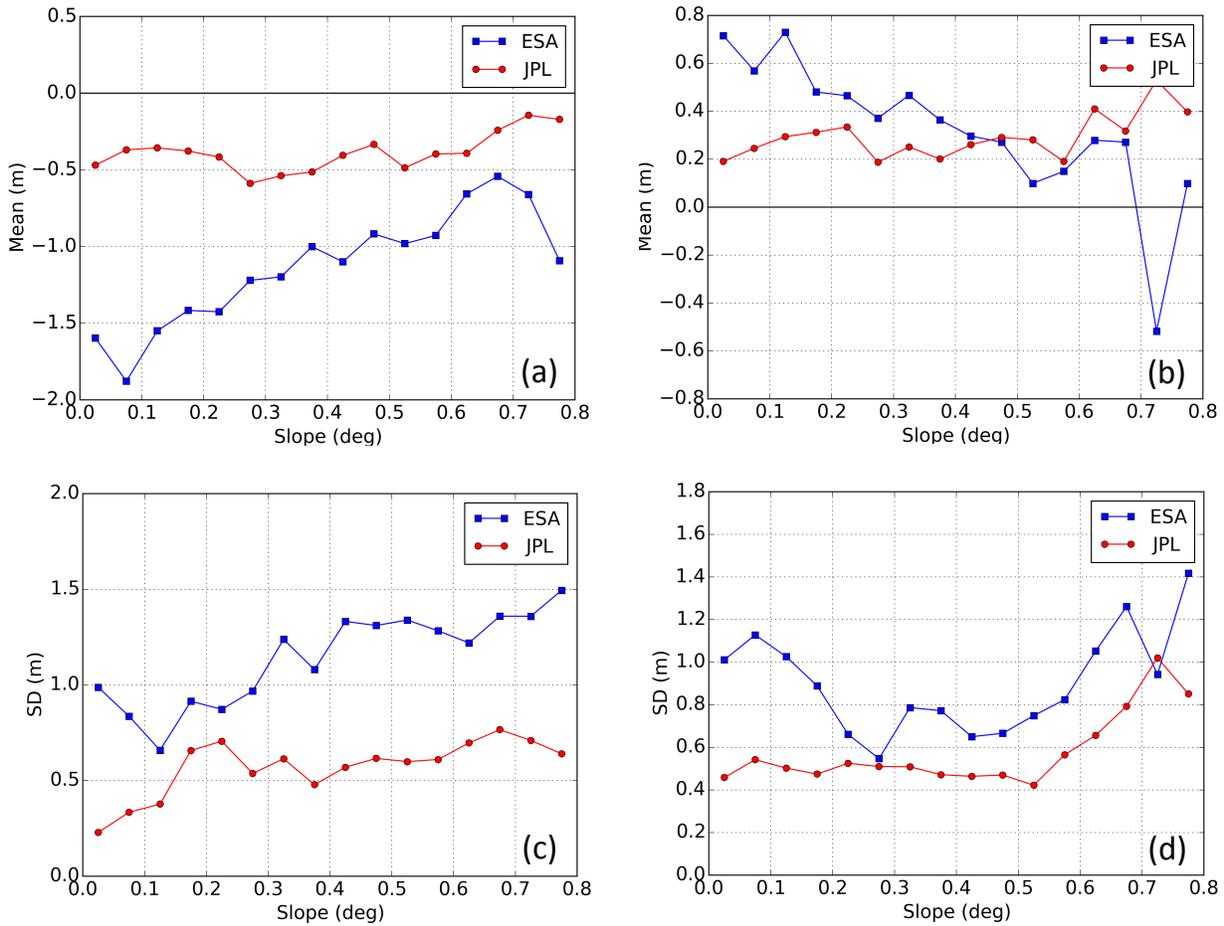

969
 970

971 *Table 4: Individual basin volume changes (km^3a^{-1}) for the Surface-Fit (SF) and Crossover (XO)*
 972 *method for the JPL and ESA product for the time period Jan-2011 to Jan-2015, with*
 973 *corresponding volumetric error.*

Basin	SF – JPL	XO – JPL	SF - ESA	XO - ESA
1	-26 ± 8	-23 ± 12	-9 ± 14	-11 ± 15
2	5 ± 8	0 ± 13	31 ± 16	30 ± 16
3	-38 ± 9	-34 ± 19	-46 ± 16	-31 ± 23
4	-36 ± 7	-37 ± 15	-42 ± 12	-16 ± 18
5	-19 ± 4	-27 ± 11	-19 ± 7	-6 ± 13
6	-72 ± 7	-71 ± 12	-75 ± 13	-79 ± 18

Figure 5: Estimated seasonal amplitude (a,c) and phase of the maximum amplitude (b,d) from the surface-fit method for CryoSat-2 [ESA (blue) and JPL (red)] compared to ICESat (ICE, black)). Values are compared using a search radius of 500 m, using the closest point within this distance, and the phase offset is referenced from 1st of January. The values of amplitude and phase are then binned according to elevation using the median value within 100 m intervals.

1022
