Response to Referee 1

We thank R1 for this detailed review, which enabled us to significantly improve our article. Enclosed please find a detailed explanation of the revisions we made based on R1’s comments. For convenience, comments are in bold and our responses are in italic. Revisions made in the manuscript are presented in italic with grey background.

The work by Verfaillie et al. presents a comprehensive analysis of past and future snow conditions at a mid-elevation mountain range in the French Alps. The regional SAFRAN reanalysis and bias-adjusted RCM experiments covering three greenhouse gas emission scenarios are used to drive the Crocus snowpack model, and model simulations are compared against observations at a single measurement site. The snowpack model is employed in a multiphysics ensemble approach which allows for an assessment of the contribution of snowpack modelling uncertainty to the overall projection uncertainty. Results for a range of snow indicators are presented. Concerning the overall future degradation of the snowpack they largely confirm previous works, but also provide a number of new and useful insights that are at least valid for this specific case.

Overall, I consider the paper as a relevant and interesting piece of work. The methods and data used are comprehensively described and are well introduced (except for the downscaling and bias-adjustment method ADAMONT, which is however explained in detail in a previous paper). The methodological approach is sound and valid. The introduction and the discussion properly refer to existing works in this field, and the conclusions are well based on the results obtained. There are no language issues, and the topic clearly fits into the journal’s scope. As such, I could generally recommend a publication of the work. However, a few minor and one major issues remain, and I’d suggest to ask the authors for a revision of their work in these respects before final publication. Minor issues are listed at the end of this review.

The remaining problem with the existing manuscript is its rather technical touch and the wealth of information that is presented in terms of data sets, emission scenarios, scenario periods, methods and especially snow indicators. The comprehensiveness of the work is impressive, but the reader very easily gets lost in this large amount of information that is presented in the text, in the tables and in the figures. These information might be very useful for local stakeholders operating in this very region and being affected by snow conditions, but for a truly useful contribution to the scientific community the results and their presentation need to be much better streamlined in my opinion. The generally most interesting part of the work is probably the entire methodological approach and the possibilities that arise from it. The very detailed results for a representative elevation of 1500 m in the Chartreuse mountain range are more of a case study, and the details of their presentation should receive less emphasis. One option might be to remove parts of the analysis entirely from the manuscript and place it in an additional, accompanying publication (e.g. the multiphysics ensemble analysis which is only briefly described in the results and which has much more potential to be analyzed in more detail). Another option is to move some of the material from the main manuscript to the supplement. This could for instance concern several of the snow indicators (like onset and meltout date), that are in any case only briefly discussed.

We thank R1 for the overall positive appreciation of our work and for the suggestions for improvements. Following them, we have decided to move Tables 3 and 5 about STEDs to the supplement as those are only briefly discussed in the text. This will reduce the total number of tables in the main article. We acknowledge the wealth of information provided in this manuscript, and consider worthwhile to present both the methods and scientific results from an examplary
geographical configuration together. We also believe that the geographical location considered (Chartreuse, 1500 m altitude) has broader relevance and that conclusions reached for this case are worth being presented in detail. We agree that several aspects of the present work deserve more in-depth analysis, and this could be addressed by future publications, although some key features can already be analyzed and assessed from the present manuscript.

While we acknowledge that the content of the manuscript can indeed be considered rather dense, we value this to be a positive quality judgement rather than an issue for a scientific publication, which targets a specialized audience.

We also hope that the dense content of our manuscript will be easier to follow after several clarifications in the text. For example, the geographical setting of the case study is now better introduced and separated from the description of the observational datasets (see below). The description of the statistical post-processing was also clarified (see further).

In combination with such a streamlining, I’d suggest to put a little more emphasis on the actual processes that are responsible for the identified future changes in the snow indicators. Little is so far said about that. The Crocus model output surely provides an opportunity to do so (e.g., separate analysis of snow accumulation and snow melt amounts).

This was already approached in our paper (through the analysis of temperature and precipitation, including the phase of precipitation, as the main drivers of snowpack reduction). While interesting, a further analysis seems out of the scope of our paper, and would make it longer.

In this respect, the relation of the snow indicator changes to the GLOBAL temperature change is not very helpful and the authors should think about putting the LOCAL temperature change into focus (though I completely understand the choice of the global scale given political climate targets).

Local temperature changes are addressed in detail in the manuscript, in text, tabular and graphical formats. We acknowledge that the reviewer understands our choice to relate local changes in snow indicators to global temperature variations. The reasons and the limitations of this choice are detailed in section 4.4. We understand the reviewer encourages us to relate local changes in snow indicators to local changes in temperature. While doable and certainly leading to significant relationships (at least on 30 years average values) because the physical link is obviously more direct, we preferred not to include this in the revised manuscript in order to not lengthen it and not induce confusions between local temperature and global temperature relationships. This could be addressed in a future study, either by us or other research groups, which may be interested in exploring further results, which could be obtained on the basis of our newly derived dataset.

Such a shift of the focus away from details of the case study and towards a more methodological and process-oriented analysis would be very worthwhile in my opinion. Apart from this and as said before, I consider the manuscript as being of high quality and of general relevance for the readership of the journal.

We understand the reviewer’s point of view, and consider this manuscript to be viewed both as a methodological and application oriented manuscript. We will be pleased to introduce future publications targeting expanded application domains (entire French Alps, Pyrenees, etc.) as well as more in-depth analysis of the drivers for snowpack changes.

Minor issues ===== Spatial scale of the Crocus application: What remains somehow unclear is the spatial setup of the Crocus model. I assume the authors use a single-site setup, driven by the outcomes of the SAFRAN reanalysis and of the ADAMONT downscaling method for a representative 1500 m elevation range in the Chartreuse massif. Is that the case? If so, this needs to be clearly said and described in some more detail. It would imply
that the results shown are only valid for that specific elevation range in this massif. What about other elevations then? Is it possible to come up with some speculation here as well? Snow projections will surely strongly depend on the elevation considered, and some placement of the results into a broader spatial context would be helpful.

Yes, we use a single-site setup (Chartreuse massif at 1500 m a.s.l.). This is now better explained through a new section « 2.1 Geographical setup ». We preferred not speculating on results which could be obtained at other geographical locations and altitudes, because this would unnecessarily lengthen an already long manuscript, and will be addressed without speculation in follow-up publications. However, we added the following in the Conclusions: « (…) our results do not directly allow extrapolation of the conclusions in other mountain regions in France or other elevations, although it is expected that the response of neighbouring mountain ranges may be comparable at the same altitude level. » (p. 30 L. 25-27)

Page 1 Line 2: “investigates” instead of “introduces” is probably the better choice. This is now corrected. (p. 1 L. 2)

Page 1 Line 9: “reduction in mean interannual snow conditions” is rather unclear. We have rephrased: « reduction in average snow conditions ». (p. 1 L. 9)

Page 2 Line 30: “they” instead of “there”. This was corrected. (p. 2 L. 29)

Page 3 Line 22: The term “currently” is probably wrong. At this point, more GCM-RCM chains are available from EURO-CORDEX. The authors just either specify their date of access of the data base or justify their selection of all available model chains. We used the models available when we last accessed the database to retrieve the data before launching the whole processing chain, and for which the geopotential data for the corresponding CMIP5 GCM (necessary in the ADAMONT method for the calculation of weather regimes) were available.

This is now specified: « The 13 GCM/RCM EURO-CORDEX pairs available in April 2017 (and for which the geopotential data for the corresponding CMIP5 GCMs were available) were used. These are expected (…) ». (p. 3 L. 21-22)

And also in Section 2.3: « This study uses the EURO-CORDEX dataset (Jacob et al., 2014; Kotlarski et al., 2014) available in April 2017, consisting of (…). Only the GCM/RCM pairs for which the geopotential data for the CMIP5 GCMs were available were used. » (p. 5 L. 2-5)

Page 4 Lines 8-15: Please check: Is SAFRAN really ONLY available over mountain ranges? To my knowledge, entire France is covered.

SAFRAN refers here to the original mountain region implementation (Durand et al., 1993). SAFRAN was expanded to wider geographical areas in France (Vidal et al., 2010) and Spain (Quintana-Segui et al., 2017). This is now indicated. (p. 4 L. 21-22)

Page 8 Lines 5-21: This method description is rather confusing and very hard to follow. Please streamline.

We are sorry that the statistical post-processing appeared confusing, indeed this is a key aspect of our work and we attempted to make it clearer in the revised manuscript, which now reads (entire paragraph copied here, p. 7 L. 10-33):

« The entire model chain provides estimates of a series of annual indicators spanning continuously the historical period from 1950 to 2005, typically, to the end of the 21st century. A total of 13
GCM/RCM pairs were considered in the case of RCP4.5 and RCP8.5, out of which 4 are also available for RCP2.6. We generally used a 15-year window to assess the statistical distribution of the indicators considered. For a given GCM/RCM pair and a given RCP, statistics corresponding to a given year can be computed using indicator values for the 15 years surrounding it (7 before, the central year, and 7 after). In what follows, we assume that all GCM/RCM pairs bear equal probability (Knutti et al., 2010). We post-processed the distribution of annual indicator values in two ways.

1. Quantiles of annual values: In this case, for a given RCP, all annual values of the indicators spanning the 15 year time window for all the corresponding GCM/RCM pairs were pooled together (195 in the case of RCP4.5 and RCP8.5, 60 in the case of RCP2.6). The quantiles of the distribution of the annual values were determined using a kernel smoothing approach. We computed the 5%, 17%, 50%, 83% and 95% values (Q5, Q17, Q50, Q83, Q95), consistent with IPCC (2013). This approach provides statistical estimates for annual values of the indicator, although it mixes together the effects of interannual variability and inter-model variability.

2. Moments of multi-year averages: A running average of annual indicator values was computed using the 15 year sample window, for a given RCP and for each GCM/RCM pair. For a given RCP, mean ($\mu$) and standard deviation ($\sigma$) values were computed for the ensemble of multi-annual averages of all GCM/RCM pairs. This approach provides information on the statistical distribution of each indicator for a given RCP on a multi-annual average perspective. In practice, we compute $\sigma' = 0.95 \sigma$, corresponding to the 17% and 83% quantiles in the case of a normal distribution, so that this approach becomes more comparable to the annual quantiles approach described earlier. In the case of the multiphysics Crocus model implementation, we mostly used the multi-year averages approach, and applied it to all Crocus members.

The spread of the distributions of these two approaches can be assessed in rather similar ways. In the multi-year average approach, the coefficient of variation CV can be determined as $CV = \frac{2 \times \sigma}{\mu}$. In the annual quantiles approach, the spread can be assessed by dividing $Q83-Q17$ by $Q50$ to form a formal equivalent to the coefficient of variation, defined using quantile values instead of mean and standard deviation (referred to as quantile-based coefficient of variation -QCV-hereafter). »

Figure 1: The STEDx should represent some duration of exceedance and hence need to be represented by some horizontal range in this graph. The representation by single vertical arrows is probably wrong, please check.

We agree with this remark and have attempted to improve the graphical representation of this series of indicators.

Page 9, line 1: Temperature changes are surely not computed in a relative manner, please check.

OK. We changed the sentence to: « Changes were computed (…) ». (p. 9 L. 11)

Page 19 Lines 6-10: I assume this is simply an effect of random internal variability at decadal scale, could that be (simulations out-of-phase with reality)? Please clarify.

We agree that this is an effect of random internal variability. This is what we wrote in the original manuscript (« low frequency variations at the decadal time scale, superimposing on a long-term trend of general snow reduction »).
Page 23 Line 31: Isn't it rather random variations (instead of systematic variations)?

*We removed the word « systematic ». (p. 25 L. 5)*

Page 25 Lines 14-16: Is this really the case? Why should a matching of quantile distributions reduce interannual variations? please check and better explain.

*The method does not reduce interannual variations, but it is clear that it will tend to reduce the spread between different GCM/RCM model results over the calibration time period. We have rephrased to: « which inevitably reduces the spread between different GCM/RCM pairs ». (p. 25 L. 22)*
Response to Referee 2

We thank R2 for this helpful review. Enclosed please find a detailed explanation of the revisions we made based on R2's comments. For convenience, comments are in bold and our responses are in italic. Revisions made in the manuscript are presented in italic with grey background.

This paper analyses the mean state and variability in historical and future snow conditions at a mid-elevation location in the French Alps. Analysis is based on output from a physical snowpack model (Crocus) driven by a regional historical reanalysis (SAFRAN) and a suite of historical and future RCM simulations. In situ observations from a nearby location are also used for comparison of the historical conditions.

The methodology used in the paper is novel and represents an improvement on previous studies. Results are generally well described compared to existing literature. However I believe there are several changes required and details to clarify before I can recommend final publication.

We thank the reviewer for this overall positive appreciation of our work and hope that our revisions and replies will address his/her concerns.

Specific Comments:

Table 1 obscures the fact that there are only 5 distinct GCMs simulations that sample natural variability. I think this should be pointed out explicitly.

We now represent Table 1 as a matrix of the different RCM/GCM combinations. (p. 6)

Figure 2a-c: In the supplementary material for the RCP8.5 scenario there is a distinct change in the stddev as average snow depth becomes small. It's therefore unfair therefore to suggest that the stddev is stationary based on the RCP4.5 scenario. I think it would be fairer to show the RCP8.5 scenario in the paper and place RCP2.6 and 4.5 in the SI.

We agree that RCP 4.5 and RCP 8.5 provide different end-of-century responses of the snowpack for virtually all indicators. It is also true that in the case of RCP 8.5, the snow reduction is sufficiently pronounced that the standard deviation can no longer be considered stationary. However, we believe that it would be unfair to choose RCP 4.5 or RCP 8.5 and focus on either one or the other in the presentation of results and analysis. We intended in the original version of the manuscript to show RCP 4.5 in the main body of the article and provide RCP 8.5 results in the supplement, for the sole sake of saving space. Based on the reviewer comment, we suggest that both RCP 4.5 and RCP 8.5 should be displayed in the main body of the revised article, so that this does not give the reader any impression that we favor one of these two RCPs.

The fact that stddev declines through time for RCP 8.5 is now indicated: « Figure 2e displays values on the order of 0.08 to 0.11 m with decadal variability but no temporal trend from 1950 to 2100. Figure 3e, on the other hand, shows a decline of standard deviation with time, as SD becomes smaller. » (p. 11 L. 24-26)

Figure 2d: The large relative contribution to combined model uncertainty arising from snowpack model multiphysics compared to RCM/GCM inter-model variability seems difficult to reconcile with plots 2a-c (I realize there is interannual variability in Figs 2a-c, while much of this signal is removed in the multi-annual average). Is it possible to present
15 year running means for the 13 RCM/GCM tracks shown in Fig 2c or at least for a representative subset of the 13 pairs along with Fig d (either in this same figure, or in a separate figure similar to how you subsequently separate quantile plots based on annual frequency data and multi-annually averaged data)? This may allow the reader to get a better sense of the relative spread in the ESCROC ensembles compared to the RCM/GCM inter-model variability.

We agree that the relative contribution of uncertainty displayed by Fig. 2d (2e in the revised manuscript) could not be directly associated with the spread of Fig. 2c because the 15-year running mean removes the high interannual variability. Therefore, we added an intermediate panel (Fig. 2d) which is simply the 15-year running mean of Fig 2c. We think that this helps the reader understand all the post-processing and the links between the different subplots.

The description of this Figure was modified accordingly in section 3.1:
« Figures 2d and 3d present the 13×35 15-year running average values spanning all simulation members of Figures 2c and 3c respectively. This corresponds to the second statistical post-processing described in Section 2.5.2 which removes the interannual variability and allows an easier quantification of each source of uncertainty. Figures 2e and 3e aim at apportioning the uncertainty in the time series of Figures 2d and 3d respectively, between the uncertainty arising from GCM/RCM inter-model variability (including model uncertainty and internal variability of climate at different time scales) and the uncertainty arising from the multiphysics snowpack model. For that purpose, the standard deviations of the 455 values of Figures 2d and 3d were computed for each 15-year window, and correspond to the total standard deviations of the SD. This is shown in black solid line in Figures 2e and 3e. (...) ».
(p. 11 L. 17-24)

Further to this point — in the text there are several times that you refer to the relative fraction of uncertainty contributed by snowpack model multiphysics as ~20%, yet this graph shows that is can be as high as 80%. Please justify the use of 20%. Is there a rationale for why the uncertainty due to snowpack model multiphysics is higher in the historical period, even though the combined model uncertainty remains fairly constant?

R2 is right that the value of 20 % uncertainty is only valid for future time periods. The answer concerning the fact that uncertainty due to snowpack model multiphysics is higher in the historical period is partly given p. 12 L. 1-3: « (...) the historical period is affected by the varying number of available GCM/RCM before 1980 and by a potentially artificial reduction of spread over the 1980-2011 calibration period of the ADAMONT statistical adjustment method ». Just after this sentence, we added this implication in the manuscript:
« This could partly explain why the uncertainty of GCM/RCM appears lower than the multiphysics uncertainty on the historical period, in combination with the deeper snowpacks in the historical period. » (p. 12 L. 3-4)

Indeed the uncertainty also declines with time linked to increased snow scarcity, as already indicated (p. 11 L. 32-35): « The ESCROC component shows values ranging from 0.02 m to 0.07 m, exhibiting rather smooth fluctuations from 1950 to 2100 and a general decreasing trend, along with the general decreasing trend of SD over the considered time period (see below) ».

Figure 3 and 4: The quantiles from different RCPs overlap too much in these figures to discern one set of shading from the others. I suggest showing RCP8.5 only in these figures. The results from the other RCP scenarios are provided in tabular form in the main document which I think is sufficient (along with the plots of other RCPs in the SI).

We do not agree to show only one RCP in the main text, and prefer to show all of them together, with individual RCP plots in the supplement. There is no rationale for choosing either one the existing RCPs.
Figure 3: Why do the SOD and SMOD for RCP8.5 begin to encompass summer months? Is this an error with the calculation?

We thank R2 for this remark. Indeed, there was an error in the calculations of SOD and SMOD for years in which SD was never greater than 5 cm. The algorithm was corrected with implications for Figs. 4-5 and S3 & S6, as well Tables 2 and 3.

P8.L15-21: Please clarify why you use a distance of +/- 1.37*sigma from the mean for the 17th and 83rd percentiles? Shouldn't the 17th and 83rd percentiles be 0.95 sigma away from the mean such that CV=1.9*sigma/mu?

We thank the reviewer for spotting this error. Indeed, the Q17 and Q83 percentiles correspond to ± 0.954 sigma distance to the median, we used an erroneous value in the original submission. All tables, graphics and text using Q17 and Q83 percentiles values from multi-annual average values have been updated accordingly. We are particularly grateful to the reviewer to have identified this error, which may have caused propagation of erroneous indications of variability and spread from our projections had it not been corrected during the review process.

P25.L28-29: Please rephrase in order to account for the relative component attributed to snowpack modeling errors in both future and historical periods.

This was rephrased : « (...), under the conditions of the Northern French Alps and after the middle of the 21st century, the uncertainty component attributed to the snowpack modeling errors alone is on the order of 20%, (...) ». (p. 25 L. 33 to p. 26 L. 1)

P27.L10: This statement depends on the RCP scenario. It is not the case for RCP8.5.

This is now clarified: «(...) and even increases in relative terms (until the middle of the century for all RCPs, and towards the end of the century for all RCPs except RCP8.5), (...) ». (p. 27 L. 13-14)

P28.L15-17: Could there also be a change in the mean density of snowfall occurring at the location?

The density of snowfall depends on temperature and wind speed during the snowfall. While this is an interesting hypothesis to test, we consider this to be beyond the scope of this article and to be addressed in a future study.

P29.L8-10: Please reword or justify the claim that snowpack modeling uncertainty is typically 20% when Figure 2d shows it can be up to 80%. I agree that it may have a smaller impact on trends.

The value of 20 % is valid only in the future. This sentence was rephrased : « Uncertainty arising from physical modeling of snow after the middle of the century can account to 20% typically of the simulation results ». (p. 29 L. 25-26)

P29.L11-17: The ADAMONT method was evaluated in a previous paper. Please be clear as to which aspects of these conclusions were accomplished in this paper.

The ADAMONT method was described and evaluated only on one RCM driven by a reanalysis in Verfaillie et al., 2017. Here we apply it to the EURO-CORDEX RCM/GCM ensemble spanning the historical period and future projections for the 21st century. This is the first published use of the method, so that it is the first evidence of the capability of the method to be used to adjust a large number of regional climate model results and provide consistent meteorological forcing data for the land surface model Crocus.

Further to this point, while you argue that your methodology is an improvement to previous studies that use delta change methods, your assessment of the results says that they, in
fact, agree with these previous studies. Under what circumstances might you expect to see differences? Is it possible to provide a direct comparison between your methodology and a delta change method for this location or to highlight statistics that would differ between the two methods?

We agree with the reviewer that our results are consistent with results obtained using delta-change methods, in French mountain regions as well as in Switzerland, as quoted in the manuscript (e.g. Castebrunet et al., Schmucki et al.). However, this consistency is only demonstrated for multi-annual multi-model trends on snow depth or snow water equivalent mean values. We strongly believe that our model chain, using the RCM chronology, will capture more appropriately potential changes in timing of precipitation, and as such could only be compared to raw output of RCM (e.g. Steger et al.). Differences would be expected under a situation where the chronology of precipitation would differ significantly in the future, because the delta-change approach would only modify the air temperature and rain/snow partitioning, but not the timing of the events. These changes in the multivariate chronology of meteorological events in the Alpine region have not been investigated in details until now to the best of our knowledge although their stationnarity is a requirement for the validity of the delta-change method. Furthermore, although our results do not exhibit significant changes in the interannual variability of the snow indicators, this is a result of our projections whereas it is only an assumption in the delta-change method.

While this could be interesting to demonstrate whether results obtained using delta-change approaches could still be employed for impact studies, we do not feel the need to perform such comparisons ourselves given that there are no arguments supporting that our approach could provide less appropriate results than a delta-change approach. We have no ressource to implement a delta-change method for the purpose of such a comparison, now that we have developed and implemented the full model chain described in this manuscript. We are, however, fully eager to communicate our data to other research groups interested in performing such a comparison in the future.

We added a paragraph at the end of Section 4.3 to explain this in more details:

« Many of the results discussed above indicate a strong consistency between our results and results obtained using delta-change methods, in French mountain regions as well as in Switzerland (e.g., Castebrunet et al., 2014; Schmucki et al., 2014). This consistency is shown for multi-annual multi-model trends on snow depth or snow water equivalent mean values, but cannot be assessed regarding the interannual variability because this is generally not addressed in these studies. The model chain implemented here, explicitly making use of the intra-seasonal and inter-seasonal RCM chronology, inherently captures more appropriately potential changes in timing of precipitation. Differences between the current study and studies based on delta-change approaches would be expected under a situation where the chronology of precipitation would differ significantly in the future, because the delta-change approach would only modify the air temperature and rain/snow partitioning, but not the timing of the events. These changes in the multivariate chronology of meteorological events in the Alpine region have not been investigated in details until now to the best of our knowledge, although their stationnarity is a requirement for the validity of the delta-change method. Furthermore, although our results do not exhibit significant changes in the interannual variability of the snow indicators, this is a result of our projections whereas it is only an assumption when applying a delta-change method. More in-depth comparisons between outputs of delta-change approaches and direct adjustments to RCM output could be carried out in the future, but are beyond the scope of this article. » (p. 27 L. 19-32)

Technical corrections/Suggestions:

I find the use of the phrase “annual-scale” a bit unnatural. I suggest using “annual indicators” as you occasionally do (P8.L15) throughout the paper.

This was corrected. (p. 1 L. 2)
Similarly, there are places in the paper where you might consider replacing the word “variation” with “change”, “response”, “difference” or “variability”, but I’m having trouble articulating a clear rule to follow in this. Variation is frequently reserved to specify a very small adjustment.

**OK. We corrected this throughout the manuscript.**

**Title: “Multi-component ensembles. . .”**

The title was changed accordingly.

P1.L2: “This article investigates the climatic response of a series of indicators for characterizing annual snow conditions and corresponding meteorological drivers at 1500 m altitude in the Chartreuse mountain range in the Northern French Alps. “

**OK. This sentence was modified as suggested by R2. (p. 1 L. 2-3)**

P2.L30: “because they are newer. . .”

**Done. (p. 2 L. 29)**

P3.L2-4. Please rephrase these two sentences to make the typical delta-change approach clearer.

We rephrased: « (...) a pre-determined difference (delta) of temperature and/or precipitation values to an observation record, based on changes computed using climate models (either global or regional). This cannot capture combined changes in temperature, precipitation and other meteorological factors, in terms of magnitude of the fluctuations and their seasonal-scale and interannual variability. ». (p. 3 L. 1-3).

**P8.L15: “Moments of multi-year averages: A running average of annual indicator values is computed (typically with a 15 year sample window), for a given RCP and for each GCM/RCM pair.”**

We changed the sentence to: « Moments of multi-year averages: A running average of annual indicator values was computed using the 15 year sample window, for a given RCP and for each GCM/RCM pair. ». (p. 7 L. 23-24)

**P9.L1 “for 15-year windows around each future time period t and each RCP r”**

We changed this sentence to : « for 15-year windows around each future time period t for the RCP r. ». (p. 9 L. 12-13)

**P9.L3: “i.e.” in place of “e.g.”**

**Done. (p. 9 L. 15)**

**P10.L19: “It highlights the significant interannual variability in observed, reanalyzed and climate model datasets.”**

**Done. (p. 10 L. 27)**

**P11.L37: “which highlights the need for appropriate data synthesis methods”. Please elaborate.**

We added the following sentence: « Indeed, it is not possible to draw conclusions or make decisions on the sole basis of such a raw ensemble of individual scenarios. ». (p. 11 L. 15-16)
P21.L10: to widen

This was corrected. (p. 21 L. 4)

P23.L27: “By definition no performance metrics pertaining to annual variations can be computed between the adjusted climate output and either observations or reanalysis data, because the two are not designed to exhibit synchronous variations.”

The sentence was corrected: « By definition no performance metrics pertaining to annual fluctuations can be computed between the adjusted climate output and either observations or reanalysis data, because the two are not designed to exhibit synchronous fluctuations. » (p. 25 L. 1-2)

OK, this was corrected. (p. 25 L. 10-11)

P25.L9-10: “or applying the final quantile mapping separately to rain and snow precipitation in order to mitigate detrimental interactions between temperature and precipitation (Verfaillie et al., 2017) . . .”

This was corrected. (p. 25 L. 16-17)

P25.L30: “Because the number of GCM/RCM model pairs was different for RCP2.6 (4) and RCP4.5 and RCP8.5 (13), we compared the statistics for indicators during the historical period based on the 4 RCP2.6 pairs alone, as well as the full ensemble of 13 GCM/RCM pairs.”

Done. (p. 26 L. 3-5)

P26.L11: “similar statistics are found for these 4 model pairs as for the full ensemble of thirteen.”

Done. (p. 26 L. 15-16)

P26.L24: I’m not sure what you mean by “snow-dry” seasons. Seasons without snow on ground or without snowfall occurring at this location at all?

We meant seasons without snow on the ground. This is now better explained: « (…) and more frequent seasons with barely any snow on the ground ». (p. 26 L. 28)

P26.L26-28: “The decreasing SD trend is also combined with a decreasing SWE trend (~ -6 kg m−2 per decade for RCP2.6, -18 kg m−2 per decade for RCP4.5 and -35 kg m−2 per decade for RCP8.5 over the period 2030-2090, Table 4) and a decreasing trend in duration of STED5 (as in Marty et al. (2017a)), STED50 and STED100 (Table5).”

We have replaced the sentence by:

« The decreasing SD trend is also combined with a decreasing SWE trend (~ -6 kg m−2 per decade for RCP2.6, -18 kg m−2 per decade for RCP4.5 and -35 kg m−2 per decade for RCP8.5 over the period 2030-2090, Table 3) and a decreasing trend of STED5 (as in Marty et al. (2017a)), STED50 and STED100 (Table S2). ». (p. 26 L. 30-33)

P27.L33: “This is all the more relevant in that none of the GCMs used for this study . . .”

Done. (p. 28 L. 18-19)
P28.L6-8: “. . . in contrast to previous studies (Durand et al., 2009a; Pepin et al., 2015). This result may stem in part from the fact that although elevation dependent warming is generally maximal in the fall and springtime, our target period covers mostly wintertime. Alternatively, this low enhancement factor could be due. . ..”

This was corrected (p. 28 L. 26-28).

P28.L26-28: “The multi-component ensemble framework makes it possible to account for the various sources of uncertainty and variability that affect future climate projections, some of which are neglected in both previous and ongoing climate change impact studies.”

Done (p. 29 L. 12-14)

P28.L32-32: Split into more than 1 sentence.

The sentence was split in two: « The multi-ensemble framework developed here draws on several RCPs (RCP 2.6, RCP 4.5 and RCP8.5), feeding several GCM model runs from the CMIP5 intercomparison exercise, which themselves feed various RCP model runs from the EURO-CORDEX downscaling exercise. Those are adjusted using the refined quantile mapping method ADAMONT against the meteorological reanalysis SAFRAN, making it possible to drive a multi-physical version of the energy balance multi-layer snowpack model Crocus. » (p. 29 L. 14-18)

P28.L32-36: “The method defines a series of annual snow and meteorological indicators that represent various aspects of winter snow conditions. . ..”

We changed the sentence to:

« The method defines a series of annual snow and meteorological indicators that represent various aspects of the winter season (…) ». (p. 29 L. 18-19)

P29.L21: “exhibit similar statistics at the interannual and multi-annual scale as the full 13-member ensemble, . . ..”

OK (p. 30 L. 5-6)

We changed the word « maintained » to « sustained » (p. 30 L. 11)

P29.L28-29: “As assessed in this study, for this location, interannual variability is larger than inter-model spread for a given RCP scenario.”

This was corrected (p. 30 L. 13-14)

P29.L32-33: “the latter leading to frequent occurrence of ephemeral or nearly snow-free conditions at the end of the century.”

OK (p. 30 L. 17-18)

P29.L35: “For example, the change in mean snow depth”

OK (p. 30 L. 20)

P30.L4: “this value changes very rapidly”: I dislike the wording that it changes "rapidly" since the changes on Figure 5 are quite linear (except for STED100). Please rephrase. I suggest something along the lines of "the magnitude consistently increases along with global mean temperature reaching reductions of 80% beyond 4 °C of global warming."
We have chosen the formulation suggested by R2. (p. 30 L. 22-23)

"These locations may be investigated in the future, based on the methodological framework introduced here and the data available in the SAFRAN reanalysis for the French Alps and Pyrenees (Durand et al., 2009b, a; Maris et al., 2009)."

(p. 30 L. 27-29)

Figure 2 Caption: “c) Ensemble of Crocus model configurations driven by the 13 RCP4.5 GCM/RCM pairs; each GCM/RCM pair is displayed with a different color.”

(p.13)

Figure 4 Caption: “Ensemble spread in 15-year running mean (μ ± σ’) of all GCM/RCM pairs for each scenario (HIST, RCP2.6, RCP4.5 and RCP8.5), along with 15-year running means of observations (1960-2016) and SAFRAN-Crocus runs (1958-2016) at CDP, for: . . . .”

(p. 18)

Figure 5 Caption: “Response of local meteorological and snow indicators to global warming level. Indicator response is computed as the difference of multi-annual means between end of century (EOC, 2071-2100), middle of century (MOC, 2041-2070), or beginning of century (BOC, 2011-2040) and the reference period (Ref, 1986-2005). Global warming level is computed as the difference in global mean surface air temperature between EOC, MOC or BOC and either the reference period (top axes) or the pre-industrial period (P-I, 1851-1880) (lower axes). Each point corresponds . . . . . Warming levels of 1.5 °C and 2 °C compared to pre-industrial are shown with the vertical dashed lines. Regression lines are shown for the response at EOC, MOC, BOC or all three periods (ALL) (except for P). Mean values. . . .”

Abstract.

This article introduces climate variations of annual-scale indicators for seasonal snow and its meteorological drivers, investigates the climatic response of a series of indicators for characterizing annual snow conditions and corresponding meteorological drivers at 1500 m altitude in the Chartreuse mountain range in the Northern French Alps. Past and future variations changes were computed based on reanalysis and observations from 1958 to 2016, and using CMIP5/EURO-CORDEX GCM/RCM pairs spanning historical (1950-2005) and RCP2.6 (4), RCP4.5 and RCP8.5 (13 each) future scenarios (2006-2100). The adjusted climate model runs were used to drive the multiphysics ensemble configuration of the detailed snowpack model Crocus. Uncertainty arising from physical modeling of snow accounts for 20 % typically, although the multiphysics is likely to have a much smaller impact on trends. Ensembles of climate projections are rather similar until the middle of the 21st century, and all show a continuation of the ongoing reduction in mean interannual average snow conditions, and maintained sustained interannual variability. The impact of the RCP becomes significant for the second half of the 21st century, with overall stable conditions with RCP2.6, and continued degradation of snow conditions for RCP4.5 and 8.5, the latter leading to more frequent ephemeral snow conditions. Variations Changes of local meteorological and snow conditions show significant correlation with global temperature variations changes. Global temperature levels on the order of 1.5°C above pre-industrial levels correspond to a 25 % reduction of winter mean snow depth (reference 1986-2005). Even larger reduction is expected for global temperature levels exceeding 2°C. The method can address other sectorial indicators, in the field of hydropower, mountain tourism or natural hazards.

Copyright statement. TEXT
1 Introduction

Snow on the ground is one of the most climate-sensitive components of the mountain environment. Indeed, temperature variations drive shifts of the partitioning between rain and snow precipitation, and are strongly linked with the magnitude of ablation processes (e.g. melt, sublimation). Scientific studies carried out over the past decades have demonstrated that large scale climate change has a profound impact on past and future snow conditions in alpine regions throughout the world (Martin et al., 1994; Beniston, 1997; Mote et al., 2005; Brown and Mote, 2009; Reid et al., 2015; Marty et al., 2017b) and in particular in the European Alps (Gobiet et al., 2014).

Besides its emotional and cultural visual role in the winter mountain landscape, snow is a critical water resource component (Bosshard et al., 2014; Lafaysse et al., 2014; Olsson et al., 2015) including hydropower (Francois et al., 2015). Furthermore, snow conditions exert major controls over winter mountain tourism (Abegg et al., 2007; Spandre et al., 2016a). Snow on the ground and its climate fluctuations are highly relevant for mountain ecosystem functioning (Boulangeat et al., 2014; Thuiller et al., 2014) and are strongly tied with the frequency and magnitude of mountain hazards such as snow avalanches (Martin et al., 2001; Castebrunet et al., 2014) and debris flows (Jomelli et al., 2015).

While a wealth of studies have addressed, with various levels of complexity, the unequivocal projected decrease of mean multi-annual snow amount along with corresponding temperature increase predicted by all existing climate change scenarios available for the European Alps (Rousselot et al., 2012; Steger et al., 2013; Gilaberte-Burdalo et al., 2014; Gobiet et al., 2014; Schmucki et al., 2014; Piazza et al., 2014; Lafaysse et al., 2014; Marty et al., 2017a), there remains a need for quantitative and authoritative information spanning various lead times at the scale of the 21st century appropriate for socio-economic stakeholders at the local, regional and national scale. This originates from the unavailability hitherto of required input information as well as a suitable methodological framework to identify and convey the information to their potential users in the most relevant and appropriate way. Indeed, many existing studies addressing future snow conditions in the European Alps rely on climate scenarios which have formed the basis of the 4th IPCC Assessment Report (AR4). While their conclusions were not contradicted by the subsequent report (IPCC, 2013, 2014a, b, c), various methodological changes and updates warrant the necessity to generate renewed estimates of the impact of future climate change on meteorological and natural snow conditions in the Alps, consistent with AR5 material and conclusions (IPCC, 2013). Firstly, IPCC global scale socio-economic/greenhouse gas emission scenarios have seen major changes from AR4 to AR5, from the SRES approach to RCP (Moss et al., 2010). Secondly, global climate models have evolved from the Coupled Model Intercomparison Project Phase 3 (CMIP3) to CMIP5 (Taylor et al., 2012) and generated novel ensembles of global climate projections (Taylor et al., 2012). Last, regional climate model outputs have recently been generated using CMIP5 climate projections as boundary conditions, providing ensemble model runs spanning the entire chronology of climate fluctuations using historical model runs and RCP-driven projections. This concerns the time period from 1950 to 2100 in the case of the EURO-CORDEX project (Jacob et al., 2014; Kotlarski et al., 2014). Existing recent literature addressing the impact of climate change on wintertime snow conditions has only in a few cases used these latest generation model results (Terzago et al., 2017; Frei et al., 2018).
Using latest generation climate models as input for impact assessments because they are newer is not per se a sufficient motivation for updating existing climate impact studies (Knutti et al., 2010). Improved methodological approaches have also the potential to lever critical limitations of existing studies. For example, several recent studies (Rousselot et al., 2012; Castebrunet et al., 2014; Schmucki et al., 2014; Marty et al., 2017a) were based on so-called, more or less sophisticated, delta-change approaches applied to meteorological conditions, employed to drive snowpack models. Using such methods, as recognized by Marty et al. (2017a), implies “that the variability does not change over time”, in particular the seasonality of meteorological conditions, such as the frequency of precipitation events and their time distribution. Indeed, such approaches consist in applying a pre-determined variation difference (delta) of temperature and/or precipitation values from to an observation record, based on variations changes computed using climate models (either global or regional). This cannot capture combined variations changes in temperature, precipitation and other meteorological factors, both in terms of magnitude but also seasonal variations of the fluctuations and their seasonal-scale and interannual variability. Given that snow conditions for a given season depend on the unfolding of meteorological conditions driving accumulation (precipitation events) and ablation of the snowpack, realistic predictions of the impact of climate change on mountain meteorological and snow conditions should instead be based on the chronology of the climate model outputs at the daily or sub-daily time resolution. However, this requires the use of downscaling and adjustment methods operating at these time scales (Déqué, 2007; Themeßl et al., 2011; Gobiet et al., 2015), in order to bridge the elevation gap induced by the difference between the spatial resolution of the regional or global climate model and the topography of the target area (Piazza et al., 2014), and to mitigate inevitable biases held by the raw climate model outputs (Christensen et al., 2008; Rauscher et al., 2010; Kotlarski et al., 2014). Last, solid assessment of the impact of climate change on snow conditions requires handling carefully uncertainty and variability sources, in order to provide balanced and relevant information to the end-users (Brasseur and Gallardo, 2016). This can be achieved by selecting relevant indicators along with their time and space aggregation principles, relying on ensembles addressing the largest possible range of uncertainty and variability sources, and employing a robust statistical analysis framework, in order to not only focus on changes in mean conditions (Marty et al., 2017a), but also higher order moments of the distribution of possible futures (Vasseur et al., 2014) and the statistical significance level of the computed trends (Castebrunet et al., 2014).

In this study, we introduce recent developments in the field of climate information related to meteorological and natural snow conditions, applied to the French mountain areas. The approach draws on the use of the ADAMONT statistical adjustment method (Verfaillie et al., 2017) applied to multiple historical (1950-2005) and future (2006-2100) EURO-CORDEX regional climate model runs spanning all relevant RCPs (RCP2.6, RCP4.5 and RCP 8.5). The 13 GCM/RCM EURO-CORDEX pairs were available in April 2017 (and for which the geopotential data for the corresponding CMIP5 GCMs were available) were used. These are expected to span the overall uncertainty resulting from GCM errors, RCM errors and climate internal variability. We used one of the longest meteorological reanalyses available in the French mountain regions - the SAFRAN reanalysis (Durand et al., 2009b) - as the reference observational dataset. Continuous hourly-resolution meteorological time series derived from RCM output by the ADAMONT statistical adjustment method are then used as input of the SURFEX/ISBA-Crocus snowpack model (Vionnet et al., 2012). Its default configuration and also, for the first time to the best of our knowledge, a recently developed multiphysical ensemble system (Lafaysse et al., 2017) are used, making it possible
to quantify snowpack model errors in the context of climate change impact assessment. We define a series of indicators for meteorological and natural snow conditions at the annual scale based on daily temperature, precipitation, snow depth and snow water equivalent data. The multi-ensemble datasets are analyzed using two specific statistical frameworks, addressing either individual annual values or multi-annual averages, which provide complementary information depending on the application.

While the framework developed here can be applied as such in all areas where the SAFRAN system has been implemented (Durand et al., 2009b; Maris et al., 2009; Quintana-Seguí et al., 2017), we focus in this article on results obtained for the Chartreuse massif in the Northern French Alps at an altitude of 1500 m. This altitude level is particularly sensitive to climate change (Martin et al., 1994; Rousselot et al., 2012; Steger et al., 2013; Lafaysse et al., 2014; Gobiet et al., 2015; Schmucki et al., 2014; Marty et al., 2017a) and it corresponds roughly to the setting of the mid-altitude long-term observational site Col de Porte (1325 m altitude, 45.3°N, 5.77°S), which has long been used to monitor and showcase the impact of climate change on mountain snowpack and provides appropriate observational records making it possible to place in context the modeling results.

2 Materials and Methods

2.1 Observations Geographical setup

This study uses meteorological data from the SAFRAN reanalysis (1958-2016, Durand et al., 2009a, b). The SAFRAN system is a regional scale meteorological downscaling and surface analysis system (Durand et al., 1993), providing hourly data of temperature, precipitation amount and phase, specific humidity, wind speed, and shortwave and longwave radiation, which provides meteorological data for different regions in the French Alps but also in the French and Spanish Pyrenees and Corsica. Unlike traditional reanalyses, SAFRAN does not operate on a grid, but on mountain regions subdivided into different polygons known as massifs (Durand et al., 1993, 1999), which correspond to regions of 500 to 2,000 km² for which meteorological conditions are assumed spatially homogeneous but varying only with altitude. SAFRAN data are thus available for each massif and for elevation bands with a resolution of 300 m. While all the developments and results introduced below can be generically applied to all the French mountain regions, we focus solely, for the sake of brevity, on the Chartreuse massif at an altitude of 1500 m, on flat terrain and without accounting for specific topographical masks.

Additionally, we use long-term observations from the Col de Porte observatory (CDP, 1325 m above sea level (a.s.l.), 45.3°N, 5.77°E), located in the Chartreuse massif in the French Alps (Morin et al., 2012).

2.2 Observations

2.2.1 SAFRAN reanalysis

The SAFRAN system is a regional scale meteorological downscaling and surface analysis system (Durand et al., 1993), providing hourly data of temperature, precipitation amount and phase, specific humidity, wind speed, and shortwave and longwave
radiation. SAFRAN refers here to the original mountain region implementation (Durand et al., 1993). SAFRAN was expanded to wider geographical areas in France (Vidal et al., 2010) and Spain (Quintana-Seguí et al., 2017). In this study, we use data from 1958 to 2016 for the single-site setup of the Chartreuse massif at 1500 m a.s.l., on flat terrain.

### 2.2.2 Col de Porte observations

Additionally, we use long-term observations from the Col de Porte observatory. Daily snow depth and meteorological measurements (temperature and precipitation) are available from 1960 to 2016. At this site, the snow season generally extends from December to April, with occasional occurrences of snowmelt and rainfall events, and usually low wind speed. Note that the Col de Porte meteorological observations are not used in the SAFRAN reanalysis.

### 2.3 Climate projections

This study uses the currently available EURO-CORDEX dataset (Jacob et al., 2014; Kotlarski et al., 2014) available in April 2017, consisting of 6 regional climate models (RCMs) forced by 5 different global climate models (GCMs) from the CMIP5 ensemble (Taylor et al., 2012) over Europe, for the historical, RCP 2.6, RCP 4.5 and RCP 8.5 scenarios (Moss et al., 2010). Only the GCM/RCM pairs for which the geopotential data for the CMIP5 GCMs were available were used. Historical runs generally cover the period 1950–2005 and RCPs cover the period 2006–2100, with some exceptions due either to the availability of the RCM or of the GCM. Table 1 provides the different GCM/RCM combinations used in this study. In total, 43 different 0.11° resolution (EUR 11, ≈ 12.5 km) time series of daily minimum and maximum temperature, total precipitation, longwave and shortwave incoming radiation, zonal and meridian near-surface wind speed and specific humidity were used. In order to analyze continuous long-term series (generally from 1950 to 2100 with a few exceptions), historical (HIST) and each RCP time series were concatenated (named RCP2.6, RCP4.5 and RCP8.5 in the following). The spread of this ensemble for a given RCP is due to three distinct factors: the different responses among the GCMs to a given RCP, the different responses among RCMs to a given GCM forcing, and the internal variability of climate at different time scales affecting the response of one specific model run. As in most impact studies based on EURO-CORDEX scenarios, we assume here that the 13 GCM/RCM pairs reasonably sample the overall uncertainty resulting from these 3 sources, even though not all GCM/RCM combinations are available.

The EURO-CORDEX raw surface fields were adjusted using the ADAMONT method, which is a quantile mapping and disaggregation method taking into account weather regimes to provide multi-variable hourly adjusted climate projections (Verfaillie et al., 2017). The method uses a meteorological observational dataset at hourly time resolution (here the SAFRAN meteorological reanalysis from 1980 to 2011), and regional climate model outputs covering the geographical domain of interest (here the EURO-CORDEX dataset). Raw RCM outputs for the grid point closest to the middle of the Chartreuse massif were used (see Verfaillie et al., 2017 for details). The altitude values of the RCM grid points used range from 612 to 1085 m, with a mean value across all RCMs of 880 m. Note that Verfaillie et al. (2017) have demonstrated that the ADAMONT method provides adequate results under this setting with several hundreds of meters difference between RCM and the target altitude, and that selecting RCM grid points with a larger geographical distance but lower altitude difference does not necessarily improve the outcome of the adjustment procedure.
Table 1. EURO-CORDEX GCM/RCM combinations used in this study (rows: RCMs, columns: GCMs), with the time period available for each scenario: the **HIST** and **RCP 4.5** and **8.5** scenarios (RCPs). Model combinations additionally using **RCP 2.6** are displayed in **bold**. 2.4 Snowpack model

We used the Crocus (Vionnet et al., 2012) unidimensional multilayer snowpack model to predict snow conditions based on meteorological input data (both reanalysis and adjusted climate projections). Crocus computes the exchanges of energy and mass between the snow surface and the atmosphere and between the snowpack and the ground underneath. It requires sub-diurnal (ideally hourly) meteorological forcing data and is able to simulate the evolution of the snowpack over time, by accounting for several processes occurring in the snowpack, such as thermal diffusion, phase changes, metamorphism, etc. In this study, we used the ESCROC (Ensemble System CROCus) multiphysics approach described in Lafaysse et al. (2017), which consists in using multiple combinations of different physical options of the model to build an ensemble of model configurations. We specifically use ensemble $E_2$ as defined in Lafaysse et al. (2017) which includes a subset of 35 configurations selected to be equiprobable at CDP. The spread of this ensemble has been optimized at CDP and is able to explain about 2/3 of total error in simulations driven by meteorological measurements at CDP, which is a realistic contribution of snowpack model error to the total simulation error (Raleigh et al., 2015; Lafaysse et al., 2017). An additional configuration corresponding to the default Crocus configuration run was also used, totalling 36 model configurations.
2.5 Indicators and post-processing

2.5.1 Definition of indicators

Based on meteorological and snow-related variables at daily time resolution, we computed and analyzed different indicators defined at the annual time scale, using an indicator-oriented approach described in Strasser et al. (2014). Defining "winter" as the period from December to April inclusive (5 months long), the following snow condition indicators were computed: mean winter snow depth ($\bar{SD}$), exceedance duration over a snow depth threshold for thresholds values of 5 cm, 50 cm and 1 m ($STE_D_{5}, STE_D_{50}, STE_D_{100}$, expressed in days). In terms of meteorological indicators, given the focus of the present study on wintertime processes and snow conditions, we considered mean winter temperature ($\bar{T}$), cumulated winter total (rain and snow) precipitation ($\bar{P}$) and mean winter ratio between snow and total precipitation ($\bar{R}$). Relaxing the focus on the winter time period, we also computed the maximum annual snow water equivalent ($\hat{SWE}$) as well as the snowpack onset and melt-out dates ($SOD$ and $SMOD$), which correspond to the earliest/latest time bounds of the longest period of time with snow depth values exceeding 5 cm, which can be interpreted as the longest period of time with continuous snow cover. These indicators are meant to represent the most significant features of natural snow on the ground at the annual scale (Schmucki et al., 2014), although they are not immediately relevant for snow conditions in ski resorts (Spandre et al., 2016a) and should not be the sole source of information to be used in this context. Figure 1 provides an overview of the snow-related indicators introduced above.

2.5.2 Statistical post-processing of indicators

The post-processing of the annual indicators was performed in two complementary ways, described below, using all available EURO-CORDEX entire model chain provides estimates of a series of annual indicators spanning continuously the historical period from 1950 to 2005, typically, to the end of the 21st century. A total of 13 GCM/RCM pairs and assigning them, for a given RCP, were considered in the case of RCP4.5 and RCP8.5, out of which 4 are also available for RCP2.6. We generally used a 15-year window to assess the statistical distribution of the indicators considered. For a given GCM/RCM pair and a given RCP, statistics corresponding to a given year can be computed using indicator values for the 15 years surrounding it (7 before, the central year, and 7 after). In what follows, equal weight (Knutti et al., 2010), i.e. equal probability to represent past climatic conditions (historical model runs) and possible future conditions. What follows applies for each Crocus model configuration, i.e. the handling of multiphysics snowpack model data corresponds to multiple instances of similar data processing, we assume that all GCM/RCM pairs bear equal probability (Knutti et al., 2010). We post-processed the distribution of annual indicator values in two ways.

1. Quantiles of annual values: In this case, for a given RCP, all annual values of the indicators spanning a given time window (the 15 years typically) year time window for all the corresponding GCM/RCM pairs (13 were pooled together (195 in the case of RCP4.5 and RCP8.5, 460 in the case of RCP2.6) were pooled together and. The quantiles of the distribution of the values (195 in the case of RCP4.5 and RCP8.5, 60 in the case of RCP2.6) annual values were determined using a kernel
Figure 1. Overview of the snow-related indicators introduced in section 2.5, using an arbitrary SWE and snow depth time series over the course of a given year. Top: SWE time series, displaying the maximum value $\hat{SWE}$. Bottom: snow depth time series, displaying graphically the related indicators. See text for details.
smoothing approach. We computed the 5%, 17%, 50%, 83% and 95% values (Q5, Q17, Q50, Q83, Q95), consistent with IPCC (2013). This approach has the advantage of providing statistical estimates for individual annual values of the indicator, although it mixes together the effects of interannual variability and inter-model variability. The spread resulting from these two sources of uncertainty and variability can be approached in relative terms, by dividing Q83-Q17 by Q50 to form a formal equivalent to the coefficient of variation, defined using quantile values instead of mean and standard deviation (referred to as quantile-based coefficient of variation, QCV, hereafter).

2. Moments of multi-annual averages: In this case, the multi-annual multi-year averages: A running average of annual indicator values (was computed using the 15 time windows years typically) is computed year sample window, for a given RCP and for each GCM/RCM pair. For a given RCP, mean (µ) and standard deviation (σ) values were computed for the ensemble of multi-annual averages of all GCM/RCM pairs. This approach provides information on the statistical distribution of each indicator for a given RCP on a multi-annual integration average perspective. In practice, we compute \( \sigma' = 1.37 \sigma \) or \( \sigma' = 0.95 \sigma \), corresponding to the 17% and 83% quantiles in the case of a normal distribution, so that this approach becomes more comparable to the quantile approach. The annual quantiles approach described earlier. In the case of the multiphysics Crocus model implementation, we mostly used the multi-year averages approach, and applied it to all Crocus members.

The spread of the distributions of these two approaches can be assessed in rather similar ways. In the multi-year average approach, the coefficient of variation CV can be determined as \( \text{CV} = 2 \times \sigma'/\mu \), which makes it comparable with the QCV definition above. In the annual quantiles approach, the spread can be assessed by dividing Q83-Q17 by Q50 to form a formal equivalent to the coefficient of variation, defined using quantile values instead of mean and standard deviation (referred to as quantile-based coefficient of variation, QCV, hereafter).

2.5.3 Variations of indicator values Changes between reference and future time periods

For both methods, results over the historical period are contextualized with temporal median or mean of the annual indicators computed for the SAFRAN-Crocus reanalysis and for observations at CDP.

The values of the post-processed indicators were computed using sliding 15-year windows spanning the entire climate dataset available, i.e. from 1950 to 2100 in the case of EURO-CORDEX data (although some GCM/RCM pairs do not span the full historical period), from 1958 to 2016 in the case the SAFRAN-Crocus reanalysis, and from 1960 to 2016 in the case of CDP observations. In order to compute variations differences between conditions of the recent past and future changes, the reference period 1986-2005 (Ref) was selected, which contains all (and only) historical EURO-CORDEX model runs and was used as a baseline period of the IPCC AR5. Specific values of the post-processed indicators were computed for a series of representative future 15-year time windows \( t \) centered on 2030, 2050, 2070 and 2090. For the snowpack indicators, values are provided for the reference time period as well as for the future. Relative changes were computed in the case of meteorological indicators \( T, P \) and \( R \). For each GCM/RCM pair \( m \) the mean value over the period 1986-2005 (\( \bar{x}_{m}^{0} \)) was calculated, as well as mean values for 15-year windows around each future time period \( t \) for the RCP \( r \) (\( \bar{x}_{t}^{m,r} \)). For temperature and the
ratio between snow and total precipitation, \( \Delta^{m,r}_{t} \) corresponds to the difference between \( \bar{x}^{m,r}_{t} \) and \( \bar{x}^{m}_{0} \), while for precipitation, \( \rho^{m,r}_{t} \) corresponds to the percentage increase or decrease compared to the reference period, i.e., \( (1 - \frac{\bar{x}^{m,r}_{t}}{\bar{x}^{m}_{0}}) \times 100 \).

Finally, \( \mu \pm \sigma' \) values of all \( \Delta^{m,r}_{t} \) or \( \rho^{m,r}_{t} \) for a given \( r \) and a given \( t \) were determined. These calculations were performed for each RCP using all available GCM/RCM pairs. For the reference period 1986-2005 and future time periods, the multi-model calculations were performed using either all the GCM/RCM pairs providing RCP2.6, RCP4.5 and RCP8.5 model runs (4), or all the GCM/RCM providing RCP4.5 and RCP8.5 model runs (13).

### Variations of Relationships between local indicators and global air temperature between reference and future time periods

For the reference period 1986-2005 and for three 30 year periods during the 21st century (beginning of century (BOC), 2011-2040, middle of century (MOD) 2041-2070 and end of century (EOC), 2071-2100), we computed interannual mean values corresponding to a given GCM/RCM pair for the meteorological and snow indicators introduced above, for all RCPs available for a given GCM/RCM pair (either RCP4.5 and RCP8.5 only, or all three RCP2.6, RCP4.5 and RCP8.5 scenarios). For each GCM/RCM model run under each available RCP configuration, the global temperature difference between future time periods (BOC, MOC and EOC, respectively) and the pre-industrial period (1851-1880), referred to as \( \Delta T_{g,BOC-PI} \), \( \Delta T_{g,MOC-PI} \) and \( \Delta T_{g,EOC-PI} \), respectively, for the corresponding GCM and RCP was calculated (Taylor et al., 2012). In addition, the global temperature difference was also computed between future periods (BOC, MOC and EOC) and the reference (Ref) period 1986-2005 \( \Delta T_{g,BOC-Ref} \), \( \Delta T_{g,MOC-Ref} \) and \( \Delta T_{g,EOC-Ref} \), respectively. Based on these datasets, we computed linear regressions curves (intercept forced to 0) between interannual means of the local meteorological and snow indicators during BOC, MOC and EOC, and the corresponding global annual temperature difference between the corresponding time period and the Ref period. Linear regressions were also computed using all future time periods together (ALL). In addition, the future values of the local meteorological and snow indicators of all future time periods were binned according to the corresponding global temperature by steps of 0.5°C (± 0.25°C), and the mean and standard deviation of all values within a given bin were computed.

### Comparison between results of numerical simulations and observations

On the basis of the annual values of the indicators \( SD \), \( \bar{T} \) and \( \bar{P} \) for the time period from 1986 to 2005, statistics of the differences between reanalysis data and Col de Porte observations were computed, in terms of mean bias, root mean square deviation (RMSD) and correlation (only \( \bar{T}, \bar{P} \)). This is not meant to represent an evaluation of the SAFRAN-Crocus reanalysis, because the SAFRAN dataset used in this study was not optimized to correspond exactly to the geographical setting of the Col de Porte observation site (appropriate altitude, specific terrain masks impacting solar radiation time distribution). However, the geographical setting of the observations and simulations are sufficiently close to each other that the two can be analyzed concurrently and provide reasonable information pertaining to the ability of the model chain to represent meteorological conditions in such a mountainous area. A better statistical match between observation and reanalysis would however be expected.
using meteorological data more applicable to the observation configuration, which is not the purpose of this article and was addressed in previous publications (Durand et al., 2009b; Lafaysse et al., 2013).

3 Results

This study introduces multi-component ensembles of past and future simulations of meteorological and snow conditions in the Chartreuse mountain range in the Northern French Alps at 1500 m altitude. As described previously, simulations encompass multiple RCPs, multiple GCM/RCM pairs from the EURO-CORDEX database adjusted using the ADAMONT method, and multiple Crocus snowpack model runs using the ESCROC ensemble system. This section describes the wealth of information generated through this process, focussing on meteorological and snow indicators described previously and addressing various components of the uncertainty and variability sources affecting the simulations.

3.1 Full ensemble configuration and uncertainty apportionment

Figure ?? provides Figures 2-3 provide an overview of all sources of uncertainty and variability accounted for in this study, in terms of snow conditions (using the SD indicator as an example) for the period from 1950 to 2100. Only RCP4.5 and RCP8.5 climate projection data are considered here, for the sake of brevity. The corresponding figure for RCP8.5 is available in the Supporting Information (Fig. S1) respectively.

Figure ??a shows Figures 2a and 3a show continuous time series of annual values of mean winter snow depth data (SD), either observed or generated by the default snowpack model configuration fed by meteorological data from a reanalysis or an adjusted RCM. It highlights for RCP4.5 and 8.5. They highlight the significant interannual variability both in observed, reanalyzed and climate model datasets. For the time period 1986-2005, the mean observed SD value is 0.64 m. Using the default Crocus configuration fed by the SAFRAN reanalysis at 1500 m altitude yields bias and RMSD values of annual SD values of 0.10 m and 0.18 m, respectively, against the Col de Porte observational record, which falls within the commonly accepted range of snowpack modeling errors at observing stations when models are driven by meteorological observations (Essery et al., 2013; Lafaysse et al., 2017). The mean observed T value over the same period is 0.9 °C, with bias and RMSD values of -0.1 °C and 0.6 °C, respectively, when comparing SAFRAN with the Col de Porte observational record. The coefficient of determination between SAFRAN and the observations is equal to 0.85. For P, the mean observed value is 777 kg m⁻², with a bias value of 7 kg m⁻² and a RMSD value of 149 kg m⁻². The coefficient of determination is equal to 0.74. The interannual variations fluctuations among GCM/RCM are only correlated between RCMs forced by the same GCM but decorrelated between the different GCMs, as expected.

Figure ??b shows Figures 2b and 3b show, both using meteorological reanalysis and adjusted climate model data (here one given GCM/RCM pair under RCP4.5 and RCP8.5 climate conditions), the spread of SD values which can be obtained using the ESCROC E₂ ensemble of snowpack model configurations (Lafaysse et al., 2017). The interannual variations fluctuations are highly correlated between members because they are mainly driven by the GCM/RCM used as input. The plot shows plots
show by how much the snowpack modeling uncertainty affects the results in terms of mean annual snow depth under one two specific climate scenario (one RCP two different RCPs, one GCM/RCM pair).

Figure 2c shows Figures 2c and 3c show the ensemble of Crocus model configurations driven by the 13 GCM/RCM pairs in the case of RCP4.5 and RCP8.5, each GCM/RCM pair being displayed with a given color. This figure shows the large multi-components of individual annual data which can be generated when combining all available information, which highlights the need for appropriate data synthesis methods. Indeed, it is not possible to draw conclusions or make decisions on the sole basis of such a raw ensemble of individual scenarios.

Figure 2d aims Figures 2d and 3d present the 13×35 15-year running average values spanning all simulation members of Figures 2c and 3c respectively. This corresponds to the second statistical post-processing described in Section 2.5.2 which removes the interannual variability and allows an easier quantification of each source of uncertainty.

Figures 2e and 3e aim at apportioning the uncertainty components in the time series of Figures 2d and 3d respectively, between the uncertainty arising from GCM/RCM inter-model variability (including model uncertainty and internal variability of climate at different time scales) and the uncertainty arising from the multiphysics snowpack model uncertainty. This figure is based on the multi-annual averages approach described in Section 2.5. For this, 13×35 15-year running average values of \( \bar{SD} \) values were generated, spanning all GCM/RCM combinations for RCP4.5 (13) and multiphysics Crocus ensemble ESCROC (35). The standard deviation of these, For that purpose, the standard deviations of the 455 values was of Figures 2d and 3d were computed for each 15-year window, and correspond to the total standard deviation deviations of the \( \bar{SD} \) historical and future climate conditions. This is shown in black solid line on Figure 2d, displaying in Figures 2e and 3e. Figure 2e displays values on the order of 0.08 to 0.11 m with decennial variability but no temporal trend from 1950 to 2100. This Figure 3e, on the other hand, shows a decline of standard deviation with time, as \( \bar{SD} \) becomes smaller. This standard deviation can be viewed as the total quantified uncertainty level for a given RCP affecting individual values of 15-year averages of \( \bar{SD} \). The snowpack multiphysics (referred to as ESCROC) and GCM/RCM uncertainty components were computed based on a further post-processing of the 455 \( \bar{SD} \) 15-year averages for each 15-year window. The ESCROC component was quantified as the mean value of the 13 values (one for each GCM/RCM pair) of the standard deviation of the 35 multiphysics configurations. Similarly, the GCM/RCM component was quantified as the mean value of the 35 values (one for each multiphysics configuration) of the standard deviation of the 13 GCM/RCM pairs. Time variations series of these individual values are displayed in Figure 2d Figures 2e and 3e. The ESCROC component shows values ranging from 0.05 to 0.02 m to 0.07 m depending on the RCP scenario considered, exhibiting rather smooth variations fluctuations from 1950 to 2100 and a general decreasing trend, along with the general decreasing trend of \( \bar{SD} \) over the considered time period (see below). In contrast, the GCM/RCM component shows significant variations spread, with values from 0.02 m to 0.11 m. Note that the assessment of this component for the historical period is affected by the varying number of available GCM/RCM before 1980 and by a potentially artificial reduction of spread over the 1980-2011 calibration period of the ADAMONT statistical adjustment method. This could partly explain why the uncertainty of GCM/RCM appears lower than the multiphysics uncertainty on the historical period, in combination with the deeper snowpack in the historical period. The relative proportion of these two components was estimated as the simple ratio of the corresponding variance values to the total variance value. The variance is used in this comparison
because the variances of both factors would be additive if they were independent (the interaction term is neglected here). It shows that the ESCROC component plays in the future period a smaller role than the GCM/RCM component, decreasing over time. This shows that the uncertainty arising from snowpack modeling errors plays a significant (always more than 15% of variance), although secondary role, for future climate projections. Furthermore, we anticipate that the impact of snowpack modeling uncertainties plays an even smaller role when focusing on relative changes of simulated snow conditions because for one given GCM/RCM the different ESCROC members are usually ranked in a similar order all along the simulation period. For these reasons, we focus below on modeling results solely using the default Crocus model configuration and not the multiphysics ensemble. This is further discussed in the Discussion section.

3.2 Projections of multi-RCP annual quantile values

Fifteen-year sliding quantiles for annual indicators of snow and meteorological conditions are displayed in Fig. 4. Figures for each RCP taken separately are available in the Supporting Information (Figs. S2-S4). Values for specific time periods (highlighted in Fig. 4) are provided in Tables S1-S3 of the Supporting Information.

Quantile values (Q17 = 17%, Q50 = 50%, Q83 = 83%) over 15-year windows, for the reference period 1986-2005 (Ref) in observations (OBS, only Q50), SAFRAN Crocus (S-C, only Q50) and historical scenario (HIST, *13 GCM/RCM pairs, **4 GCM/RCM pairs corresponding to the ones in RCP2.6), and around the time slots 2030, 2050, 2070 and 2090 for each future scenario (RCP2.6: 4 pairs, RCP4.5 and RCP8.5: 13 pairs), for \textit{STED}_0, \textit{STED}_50, \textit{STED}_100 (number of days). Time slot Q17 Q50 Q83 Q17 Q50 Q83 Q17 Q50 Q83 OBS 135 96 39 Ref S-C 142 103 37 HIST* 111 136 151 33 90 130 0 27 82 HIST** 106 137 153 28 93 134 0 30 81 2.6 93 121 144 17 63 113 0 11 49 2030 4.5 94 123 141 18 62 111 0 13 65 8.5 87 119 141 13 65 112 0 12 58 2.6 83 120 147 13 69 118 0 13 49 2050 4.5 77 111 136 4.39 91 0.5 32 8.5 55 98 132 0 32 83 0 4 26 2.6 92 119

Fig. 4 shows the significant interannual variability in snow and meteorologically related indicators in the observations and SAFRAN reanalysis. The observation and reanalysis indicators for snow and meteorological conditions exhibit variations which span the entire range of variations covered by climate projections, under both historical and early-21st century RCPs (the transition between historical and RCP occurs in 2005, which current observations and reanalysis overcross). This indicates that the historical and early-21st century RCPs are consistent with the observed range and interannual variability at the considered location, which corroborates the use of the EURO-CORDEX regional climate simulations together with the ADAMONT method and the Crocus snowpack model to address past and future changes of snow conditions in this mountainous area.

For the reference period 1986-2005, the median of annual values of SD, snow onset date (SOD) and snow melt-out date (SMOD) is consistent between observations, reanalysis and simulations driven by adjusted historical climate model simulations (HIST using 13 GCM/RCM pairs), with some differences. For example, as can be observed in Table 2, while the SOD median value is similar between observations and simulations (within 1 day), the SMOD median value occurs approximately 10 days later in the reanalysis than in observations, consistent with the 3 cm deviation between the median value of 8.5 cm and 11.0 cm in the observations and SAFRAN reanalysis, respectively.
Figure 2. Observed and simulated time series of $\overline{SD}$. a) Continuous time series of annual values of mean winter snow depth data ($\overline{SD}$), either observed or generated by the default snowpack model configuration fed by meteorological data from a reanalysis or an adjusted RCM. b) $\overline{SD}$ values obtained using the ensemble of Crocus model configurations ESCROC. c) Ensemble of Crocus model configurations driven by the 13 RCP 4.5 GCM/RCM pairs in the case of RCP4.5, each GCM/RCM pair being displayed with a given different color. d) 15-year running average values of all simulation members presented in c. e) Estimate of absolute and relative contribution of uncertainty components arising from GCM/RCM inter-model variability and multiphysics snowpack model uncertainty (ESCROC).
Figure 3. Same as Figure 2, but using RCP 8.5 GCM/RCM pairs.
Figure 4. Quantile values (5%, 17%, 50%, 83% and 95%) over 15-year windows of all GCM/RCM pairs (HIST, RCP2.6, RCP4.5 and RCP8.5), along with annual values of observations (1960-2016) and SAFRAN-Crocus runs (1958-2016) and their respective 15-year running medians (bold full and dotted lines respectively), for: a) $\overline{SD}$, b) $SOD$ and $SMOD$, c) $\overline{T}$, and d) $\overline{P}$. Light grey bars indicate the reference period 1986-2005 and the time slots used in Tables 2-4 and S1-S2.

reanalysis-driven and observed $\overline{SD}$. Simulations driven by adjusted historical climate model runs indicate slightly less snow than observations and reanalysis. Similar features can be identified in terms of $\text{STED}$ values in Table ??S1 of the Supporting Information.

In the case where a smaller number of GCM/RCM pairs are considered for the same time period HIST, i.e. when only the 4 GCM/RCM pairs for which RCP2.6 model runs are available and not the 13 GCM/RCM pairs for which RCP4.5 and RCP8.5 are available, the indicators calculated for the reference period only taking into account the 4 model pairs available in RCP2.6 (HIST** in Tables 2 and S1) show very small deviation to the values obtained with 13 GCM/RCM pairs. Quantile values differ by up to 3 cm for $\overline{SD}$ ($\approx$10%), 14 kg m$^{-2}$ for $\overline{\text{SWE}}$ ($\approx$6%) and 3 days for $\text{SOD}$ and $\text{SMOD}$. For $\text{STED}$ quantile values, the largest difference is 5 days ($\approx$15%). This shows that in terms of statistical distributions of annual values of the indicators, the sub-ensemble of four GCM/RCM pairs for which RCP2.6 are available exhibits similar statistical features than the full ensemble of 13 GCM/RCM pairs, in terms of mean trends and spread.
At the scale of 20-year spaced future intervals provided in Tables 2 and S1, all snow-related indicators exhibit a trend towards gradually increased snow scarcity. $SD$, $SWE$ quantile values sampled every 20 years generally decrease, $SOD$ increases (later snow onset) and $SMOD$ decreases (earlier snow melt-out date), and $STED$ values decrease. In most cases, climate projections for the 15-year periods centered around 2030 and 2050 depend only slightly if at all on the RCP. The periods centered around 2070 and 2090 show significant deviations between RCPs, with reinforced downwards trends for RCP8.5-based indicators, pursued decrease under RCP4.5 and stabilization or reduced decreasing trend for RCP2.6. In comparison to the historical model runs during the reference period 1986-2005, not only the median but also the individual quantile Q17 and Q83 values decrease. However the interquantile Q83-Q17 value remains rather constant throughout the century, in comparison with the reference period, except in the late 21st century under RCP8.5 where snow conditions become increasingly ephemeral.

For example, in the case of $SD$, the Q83-Q17 value of 0.72 m for the reference period varies for future conditions between 0.62 m and 0.67 m for RCP2.6, 0.50 m and 0.66 m for RCP4.5 and 0.16 m and 0.64 m for RCP8.5 (lowest value at the end of the century). The variability of snow conditions is therefore projected to remain significant, as large as currently encountered as long as snow conditions remain comparable.

The $SD$ quantile-based coefficient of variation (QCV=(Q83-Q17)/Q50) for the reference period is equal to 1.14, which means that the spread between the Q17 and Q83 quantile values, which comprise 2/3 of the values potentially obtained for a given winter, exceeds the median value itself, highlighting quantitatively how variable snow conditions can be from one winter to the next. For future conditions, QCV values are never found to be lower than the reference value, and vary between 1.46 and 1.81 for RCP2.6, 1.43 and 2.08 for RCP4.5, and 1.42 and 2.67 for RCP8.5. This indicates that, with the gradual decrease of median and other quantile values for $SD$, the interannual/intermodel variability is projected to remain significant and even increase in relative terms (compared to the median value). Very similar results can be obtained when considering $SWE$. In the case of $STED$ values, however, the situation is different especially for $STED_{50}$ and $STED_{100}$ because the number of snow-scarce winter increase will directly lower the Q83 quantile value while the Q17 quantile value is bounded by 0 and already equal to this value in the early 21st century for all RCPs for $STED_{100}$ and approaching it by the middle of the 21st century for all RCPs (including RCP2.6) in the case of $STED_{50}$.

### 3.3 Projections of multi-RCP multi-annual mean values

Figure 5 represents the mean ± $\sigma'$ for the same indicators as Fig. 4. Figures for each RCP taken separately are available in the Supporting Information (Figs. S5-S7). Tables 3-S4-S6, Table 3 and Table S2 of the Supporting Information also contain values for specific time slots and for additional indicators. Table 4 lists the relative change in $\overline{T}$, $\overline{P}$ and $\overline{R}$ for the same time slots compared to the reference period 1986-2005.

In contrast to Fig. 4, by design Fig. 5 suppresses most of the effects of the interannual variability, focussing on long-term trends and highlighting the uncertainty components originating from global and regional climate models. As illustrated in Tables 3 and S2, the uncertainty pertaining to multi-annual / multi-model averages is computed based on the standard deviation of the mean of the multi-model multi-annual averages over sliding time periods, as described above. Values for $\sigma'$ ($-1.37 \sigma \leq 0.95 \sigma$) are generally lower for the HIST 1986-2005 period than for the future periods centered on 2030, 2050,
**Figure 5.** Mean Ensemble spread in 15-year running mean ($\mu \pm \sigma'$) of all GCM/RCM combination 15-year running means among pairs for each scenario (HIST, RCP2.6, RCP4.5 and RCP8.5), along with 15-year running means of annual values of observations (1960-2016) and outputs of SAFRAN-Crocus runs (1958-2016) at CDP, for: a) $SD$, b) $SOD$ and $SMOD$, c) $T$, and d) $P$. Light grey bars indicate the reference period 1986-2005 and the time slots used in Tables 2-4 and S1-S2.
Table 3. Values for the mean ($\mu$) ± standard deviation ($\sigma'$) of 15-year running means, for the reference period 1986-2005 (Ref) in observations (OBS, only $\mu$), SAFRAN-Crocus (S-C, only $\mu$) and historical scenario (HIST, *13 GCM/RCM pairs, **4 GCM/RCM pairs corresponding to the ones in RCP2.6), and around the time slots 2030, 2050, 2070 and 2090 for each future scenario (RCP2.6: 4 pairs, RCP4.5 and RCP8.5: 13 pairs), for $\overline{SD}$, $\overline{SWE}$ and $SOD$ - $SMOD$ (mm/dd - mm/dd; for RCPs, number of days earlier or later compared to HIST* $SOD$ and $SMOD$).

2070 and 2090. For example, $\sigma'$ for $\overline{SD}$ over the HIST 1986-2005 period is equal to $0.000.06$ m, while for all future periods, it is rather on the order of $0.000.06$ - $0.170.12$ m, except for RCP8.5 towards the end of the century, with $\sigma'$ values $0.090.06$ m, but associated to significantly lower $\mu$ values on the order of 0.09-0.17 m. A similar observation can be made for $\overline{SWE}$, $SOD$, $SMOD$ and $STED$ values.

In terms of absolute values, as illustrated in Fig. 5, and indicated in Tables 3 and 22S2, the historical model runs for the reference period 1986-2005 are characterized by about the same amounts of snow on average as in the observations and reanalysis data. This is consistent with the only slight deviation observed between median values in the previous section. As shown in Fig. 5a, the decadal dynamics however differs, with snow conditions (observed and reanalyzed) showing rather stable conditions in the 1970s followed by abrupt variation change in the mid-1980s, followed by another period of relative stability.

Simulations driven by climate model data show a different pattern of $\overline{SD}$ changes, with an earlier reduction in the 1970s, followed by a relative increase in the 1980s followed by another reduction in the 1990s onwards. The length of the observation, reanalysis and historical climate records is too small to generalize, but all three sources of information point
Values for the mean ($\mu \pm \sigma'$) of 15-year running means, for the reference period 1986-2005 (Ref) in observations (OBS, only $\mu$), SAFRAN-Crocus (S, only $\mu$) and historical scenario (HIST, *13 GCM/RCM pairs, **4 GCM/RCM pairs corresponding to the ones in RCP2.6), and around the time slots 2030, 2050, 2070 and 2090 for each future scenario (RCP2.6: 4 pairs, RCP4.5 and RCP8.5: 13 pairs), for $STED_0$, $STED_m$, $STED_{100}$ (number of days). </table>
towards low frequency variations at the decadal time scale, superimposing on a long-term trend of general snow reduction.

At the scale of 20-year spaced future intervals provided in Tables 3 and S2, similarly to the results of the annual quantiles approach, all snow-related indicators exhibit a trend towards gradually increased snow scarcity. Also similarly, in most cases, climate projections for the 15-year periods centered around 2030 and 2050 depend only slightly if at all on the RCP, the periods centered around 2070 and 2090 show significant deviations between RCPs, with reinforced downwards trends for RCP8.5-based indicators, pursued decrease under RCP4.5 and stabilization or reduced decreasing trend for RCP2.6.

Similarly to the previous section, the values of the indicators are calculated for the reference period either taking into account the 4 model pairs available in RCP2.6 (HIST**) or the 13 pairs for which RCP4.5 and RCP8.5 are available, see in Tables 3-4 and S2. Mean values are only slightly impacted for some indicators (e.g. for \( \hat{SWE} \) or \( P \)). This shows that at the interannual time scales, the sub-ensemble of four GCM/RCM pairs for which RCP2.6 are available exhibits similar statistical features than the full ensemble of 13 GCM/RCM pairs, in terms of mean trends and spread.

The SD coefficient of variation (CV=\( 2 \times \sigma'/\mu \)) for the reference period is equal to 0.270.18, which illustrates well the suppression of the interannual variability effect. This corresponds to only 2416% of the QCV (see above), which indicates that for the reference period and for this case, the interannual variability of annual indicator values plays a stronger role than the inter-model spread for a given year. For future conditions, CV tends to increase, but this is more due to a decrease of \( \mu \) in all cases than to \( \sigma' \) variations, as shown above. CV remains always smaller than QCV, which indicates that, regardless of the scenario and the time period in the future, the variability/uncertainty related to the inter-model spread (for a given RCP and time period) remains always lower than the inter-annual variations.

Table 4 provides a summary of the meteorological conditions associated to the past and future snow conditions addressed in this study, in terms of multi-annual means. While the mean winter temperature value for the reference period 1986-2005 is on the order of 0.4 - 0.9 °C in the Chartreuse mountain range at 1500 m depending on whether the SAFRAN reanalysis or the historical climate runs are considered, the 15-year period centered on 2030 already exhibits a mean increase of +1.0 ± 0.4 to +1.0 ± 0.3 °C regardless of the RCP. The results for the three RCPs already differentiate for the 2050 lead time, and the difference continues to widen until the end of the century with +1.4 ± 0.5 to +1.4 ± 0.4 °C for RCP2.6, +2.3 ± 0.9 to +2.3 ± 0.6 °C for RCP4.5 and +4.6 ± 1.0 to +4.6 ± 0.7 °C for RCP8.5. While the temperature trends are unequivocal, there is no significant trend for total winter precipitation, as shown in Table 4. The snow/rain precipitation ratio is projected to evolve markedly along with the temperature rise, with a maximum reduction by 37.3 ± 5.1% of the snow precipitation share over the total winter precipitation.

### 3.4 Relationship between global temperature trends and local snow and meteorological conditions

Figure 6 shows the relationships between computed variations of the snow and meteorological indicators between 1986-2005 (reference period for this study) and three future time periods (beginning of century (BOC), 2011-2040, middle of century (MOD) 2041-2070 and end of century (EOC), 2071-2100), and the corresponding global temperature variations simulated by the driving GCM. This figure uses \( \Delta T_{g,EOC-PI} \) as a reference (lower axis). The corresponding rela-
tionship to $\Delta T_{g, EOC - Ref}$ is also shown (upper axis), which consists in a shift of 0.62°C ($\Delta T_{g, Ref - PI}$) although individual $\Delta T_{g, Ref - PI}$ values range from 0.19 to 0.84°C depending on the GCM. Regressions were however computed using the values of $\Delta T_{g, BOC - Ref}$, $\Delta T_{g, MOC - Ref}$ and $\Delta T_{g, EOC - Ref}$ for each GCM, as well as all three future periods taken together. Table 5 shows the slope (per global °C difference with the Ref value) of the variation of the change of the local indicator, as well as the coefficient of determination. With the notable exception of the cumulated winter precipitation $\overline{P}$, all indicators show consistent relationship with $\Delta T_{g}$. The slope of the regression curve is very similar for all three future time periods BOC, MOC and EOC, as well as when all future time periods are pooled together. The maximum correlation is found for the snow precipitation ratio with a coefficient of determination of 0.90, followed by local air temperature with a coefficient of determination of 0.86. The worst correlation is found for $STED_{100}$ ($R^2=0.48$ for all time periods). All snow-related indicators $R^2$ values range between 0.76 and 0.83 (for all future time periods together), with a trend to lower values for BOC only time period, and higher values for EOC and all time periods together. Taking the sum of absolute values of $SOD$ and $SMOD$ as a measure of the changes of total snow season length, it is found that the total snow season length is decreased by 29 days, i.e. about one month, per global °C difference with the Ref value. The slope of the local temperature regression curve is 1.1 °C°C$^{-1}$, which indicates that the local rate of warming only slightly exceeds the global warming rate during the 21st century, using this method.

Relating to specific target values of global surface air temperature $\Delta T_{g}$ since the pre-industrial period, Figure 6 and the data provided in Table 6 show for example that for a global temperature increase of 1.5°C compared to the pre-industrial period, the mean variation change of mean snow depth at 1500 m altitude in the Chartreuse mountain range is in the order of -25%, and this value increases very rapidly with increasing global temperature variations changes, reaching reductions of 65% for 3°C global temperature rise, and even 80% reduction passed 4°C temperature rise. However, for a given $\Delta T_{g, EOC - PI}$ value, model runs spanning several tens of % reduction rate can be sampled (e.g. around 2°C), showing that the relationship between global temperature values and local impacts is not unequivocal. This is materialized by the standard deviation provided in Table 6. The same applies in terms of trends to all local meteorological and snow indicators (except total precipitation, as noted before).

4 Discussion

This study is based on a multi-component ensemble framework in order to provide future values of meteorological and snow conditions at a typical mid-altitude (1500 m) mountain range in the Northern French Alps, accounting for these uncertainty and variability sources in the most consistent and rigorous possible manner. To this end, a multi-component ensemble framework was designed and built, addressing various sources of uncertainty and variability, i.e. several RCPs (RCP 2.6, RCP 4.5 and RCP8.5), feeding several GCM model runs from the CMIP5 intercomparison exercise, which themselves feed various RCM
Figure 6. Relationship between response of local meteorological and snow indicators to global warming level. Indicator response is computed as the variation difference of multi-annual means between end of century (EOC, 2071-2100), middle of century (MOC, 2041-2070), or beginning of century (BOC, 2011-2040) and the reference period (Ref, 1986-2005) multi-annual mean of meteorological and snow indicators with. Global warming level is computed as the corresponding variation of difference in global mean surface air temperature between EOC, over-MOC or BOC and either the reference time period (top axes) and with respect to or the pre-industrial period (P-I, 1851-1880) (lower axes). Each point corresponds to a snow or meteorological indicator computed using a given RCP and one GCM/RCM pair, for which the global surface air temperature variation change is inferred from the corresponding GCM run: a) $SD$ (%), b) $SWE$ (%), c) $SOD$ and $SMOD$ (days), d) $STED_5$ (days), e) $STED_{50}$ (days), f) $STED_{100}$ (days), g) $\bar{T}$ (°C), h) $\bar{P}$ (%), i) $\bar{R}$ (%). Warming levels of 1.5°C and 2°C compared to the pre-industrial are shown with the vertical dashed lines. The regression lines are shown for the variation between response at EOC, MOC, BOC or all three periods (ALL) and the reference period and $\Delta T_{g, EOC-P-I}$ are indicated (except for $\bar{P}$). Mean values and standard deviations among ALL variations changes of each indicator for 0.5°C $\Delta T_{g, EOC-P-I}$ intervals (± 0.25°C) are displayed as error bars.
Table 5. Slope (α, unit indicated inside brackets) and determination coefficient (R², no unit) of linear regressions of the variations of indicators between BOC, MOC, EOC or ALL and the reference period (1986-2005) and corresponding global temperature rise since 1986-2005. P is not shown. The number of values used for each regression is indicated inside brackets.

model runs as part of the EURO-CORDEX downscaling exercise, which are adjusted using the ADAMONT method against the meteorological reanalysis product SAFRAN, making it possible to drive a multi-physical version of the energy balance multi-layer snowpack model Crocus. Here we discuss the results obtained for the period from 1950 to 2100, in comparison to reanalysis and comparable observation data for the past period, and with other existing scientific studies for future conditions.

4.1 On the comparability between adjusted historical climate model runs and observations and reanalyses

As shown in section 3.1, SAFRAN and Crocus (either multiphysics or default configuration) results show acceptable performance metrics compared to in-situ observations of meteorological conditions and snow conditions, respectively. By definition no performance metrics pertaining to annual fluctuations can be computed on the basis of annual variations between the adjusted climate output and either observations or reanalysis data, and only multi-annual statistics may be compared, under certain assumptions, which is done in sections 3.2 and 3.3, for the snow indicators defined in this study. Indeed, even over a time scale of 20 years, it is likely and even expected that low frequency variability in the climate, in nature and as it is represented in GCMs, leads to systematic deviations at this time scale, which the statistical adjustment method can only partially mitigate. For the reference period 1986-2005, the match between observation and reanalysis data, and historical GCM/RCM runs is nevertheless satisfying. However, it is also clear from Fig. 4 and Fig. 5 that the match is not as good for a period extending back into the past, with a tendency for adjusted climate model data to provide reduced snow conditions compared to observed and reanalyzed data for the period before 1985. While the reasons for such a behaviour are likely multiple, it is certainly influenced by the fact that this period is almost independent from the time period used for the adjustment over which the ADAMONT method was applied for calibration of the
**Table 6.** Mean value ± standard deviation of the changes of each indicator between ALL and the reference period (1986-2005), for $\Delta T_{g, EOC-PI}$ intervals of 0.5°C. The number of values used in each interval is indicated inside brackets.

**ADAMONT adjustment method** (1980-2011), and during which major climate shifts occurred (Reid et al., 2015). This could also be due to the fact that Crocus model outputs result from the interaction between various meteorological variables, both in terms of mean values but also their day to day variations, especially precipitation and temperature conditions which together yield either to rain or snow precipitation. By design, the ADAMONT method adjusts the variables independently from each other (Verfaillie et al., 2017). Even if special care is taken to minimize the disadvantages of this approach, such as the use of weather regimes for the quantile mapping statistical adjustment method, or applying the final quantile mapping separately to rain and snow precipitation in order to mitigate detrimental interactions between temperature and precipitation (Verfaillie et al., 2017), some interaction terms probably remain uncorrected. The adjustment method also probably exerts an influence on the variability during the historical period, which may be responsible for the overall lower spread (either expressed in terms of quantile-based coefficient of variation of annual values or the coefficient of variation of the interannual means) compared to future projections. Indeed, by design the adjustment method attempts to bring reanalysis meteorological data and historical model runs to the same ground in terms of quantile distributions, which inevitably reduces the spread of interannual variations between different models. This is visible in the analyzed results, because the reference time period used 1986-2005 is included in the period used for the statistical adjustment method. In addition, the lower spread, compared to future periods of 15 years, could also be due to the fact that the reference period is longer than the future time periods considered, so that a wider range of climate conditions are sampled in the multi-annual mean, thereby bringing closer the values originating from the various RCMs.

### 4.2 Uncertainty and variability sources

The study uses multi-component ensembles to address uncertainty and variability sources, which are analyzed through indicators computed using various sub-ensembles. Based on the results shown above, it clearly appears that snowpack modeling errors, due to uncertain physical knowledge of processes at play and their imperfect implementation in the model, can be responsible for a significant fraction of the uncertainty pertaining to future climate projections, consistent with previous results obtained based on observations at instrumented sites (Essery et al., 2013; Lafaysse et al., 2017). While this must be taken into account for a fully comprehensive assessment, evidence from this study suggests that, under the conditions of the Northern French Alps and after the middle of the 21st century, the uncertainty component attributed to the snowpack modeling errors alone is on the order of 20%, which is significant but of second order compared to the spread originating from multiple climate models.

Initially motivated by the fact that the number of GCM/RCM model pairs was different for RCP2.6 (4) and RCP4.5 and RCP8.5 (13), which could lead to different multi-model statistics and the impossibility to compare them specifically, we compared the statistics for indicators based on either during the historical period based on the 4 or RCP2.6 pairs alone, as well as the full ensemble of 13 GCM/RCM pairs for the historical period. Both in terms of statistics distributions of annual values for a period of 20 years (1986-2005) or in terms of multi-model spread of multi-annual average values, results were extremely close for the full and sub-ensemble. While it remains desirable, when possible, to use the largest possible num-
number of different GCM/RCM pairs in order to mitigate the impact of multi-model variability and climate internal variability, this tends to show that, in this case, robust results can be obtained using a subset of a few models dealt with appropriately. However, as shown in Figure 6, individual GCM/RCM pairs only sample imperfectly the range of possible future climate conditions, so that choosing, randomly or not, a too small number of GCM/RCM pairs, would inevitably lead to biased results. This is consistent with the fact that the variability of snow conditions is primarily dominated by interannual variability, over which inter-model spread superimposes an additional uncertainty component. It is very likely that the 4 GCM/RCM pairs used in this study, which feature RCP2.6, RCP4.5 and RCP8.5 model results, possess appropriate interannual variability properties and overall no major deviation from the average behaviour of the full ensemble of 13 GCM/RCM pairs, which leads to the fact that similar statistics are found with these 4 model pairs than for the 13 full ensemble as for the full ensemble of thirteen. It is not certain that a similar result would be obtained by picking randomly 4 GCM/RCM pairs within the full ensemble available (see Figure 6 for contrasted individual model behaviour).

4.3 General trends and added value of the approach developed

That natural snow conditions at 1500 m in the Northern French Alps are projected to decrease under ongoing climate change is an expected result, which deserves however to be put in perspective with other existing studies on the matter. Figures 4-5 and Tables 2 and 3 indicate a general decreasing trend in $\overline{SD}$ towards the end of the century ($\approx -0.8$ cm per decade for RCP2.6, $-3.2$ cm per decade for RCP4.5 and $-6.5$ cm per decade for RCP8.5 over the period 2030-2090), accompanied by a shortening of the snow season (later $SOD$ and earlier $SMOD$). This is consistent with previous results from Steger et al. (2013) for the 1000 - 1500 m a.s.l. range in the European Alps. The magnitude of the $\overline{SD}$ decrease is similar to the one found by Marty et al. (2017a) for the Aare and Grisons regions in Switzerland, although their GCM/RCM models and future scenarios differ from ours. This trend is visible for all scenarios, but stronger for RCP8.5. At the end of the century, simulations carried out under this scenario predict an increasingly ephemeral snow cover (multi-annual mean value of $9\pm6$ cm for the 2090 time slot, see Table 3) and more frequent snow-dry seasons with barely any snow on the ground (Figs. 4-5 and Tables 2 and 3). The shortening of the snow season is projected to become asymmetric towards the end of the century, with a stronger reduction in spring than in autumn (Tables 2 and 3), similar to findings from Steger et al. (2013) and Marty et al. (2017a). The decreasing $\overline{SD}$ trend is also combined with a decrease with time of decreasing SWE trend ($\approx -6$ kg m$^{-2}$ per decade for RCP2.6, $-18$ kg m$^{-2}$ per decade for RCP4.5 and $-35$ kg m$^{-2}$ per decade for RCP8.5 over the period 2030-2090, Table 3) and a decreasing trend of $STED_5$ (as in Marty et al. (2017a)), $STED_{50}$ and $STED_{100}$ (Table ??).

Figures 4-5 also indicate a strong increasing trend in $\overline{T}$ for the 21st century ($\approx +0.08$°C decade$^{-1}$ for RCP2.6, $+0.22$°C decade$^{-1}$ for RCP4.5 and $+0.58$°C decade$^{-1}$ for RCP8.5 over the period 2030-2090), but no significant trend in $\overline{P}$. Compared to the reference period 1986-2005, $\overline{T}$ increases by $1.4\pm0.50.4$°C in 2090 for scenario RCP2.6, $2.3\pm0.90.6$°C for scenario RCP4.5 and $4.6\pm0.7$°C for scenario RCP8.5 (Table 4). Values for the change in $\overline{T}$ and $\overline{P}$ are comparable to Steger et al. (2013) and Marty et al. (2017a), even though their GCM/RCM models and future scenarios differ from ours. The insignificant trend in $\overline{P}$ and its variable sign depending on the projections is fully consistent with previous studies identifying the internal variability of climate as the main uncertainty component for precipitation in the Alpine region all along the 21st century.
(Lafayse et al., 2014; Fatiichi et al., 2014). Table 4 further shows a strong decrease in $\bar{T}$ (by 2090, $-12.0 \pm 3.4\%$ for RCP2.6, $-17.7 \pm 8.4\%$ for RCP4.5 and $-37.3 \pm 7.35\%$ for RCP8.5, compared to 1986-2005), with values very similar to Frei et al. (2018).

Beyond the general trends, which provide an unsurprising -yet required- update of previous assessments based on older climate scenarios applied to the French Alps (e.g Rousselot et al., 2012; Castebrunet et al., 2014; Piazza et al., 2014), the main added value of the approach developed here lies in its ability to capture high-order moments of possible snow futures. For example, that the year-to-year variability of snow conditions on the ground remains as large as currently, and even increases in relative terms (until the middle of the century for all RCPs, and towards the end of the century for all RCPs except RCP8.5), may be of equal, if not higher significance, to stakeholders operating in the alpine environment, than the long term trends. Such results can only be attained making use of a sufficiently large number of independent global and regional climate models, the EURO-CORDEX database corresponding to a significant achievement of the climate modeling community enabling such impact studies to take place.

Many of the results discussed above indicate a strong consistency between our results and results obtained using delta-change methods, in French mountain regions as well as in Switzerland (e.g., Castebrunet et al., 2014; Schmucki et al., 2014). This consistency is shown for multi-annual multi-model trends on snow depth or snow water equivalent mean values, but cannot be assessed regarding the interannual variability because this is generally not addressed in these studies. The model chain implemented here, explicitly making use of the intra-seasonal and inter-seasonal RCM chronology, inherently captures more appropriately potential changes in timing of precipitation. Differences between the current study and studies based on delta-change approaches would be expected under a situation where the chronology of precipitation would differ significantly in the future, because the delta-change approach would only modify the air temperature and rain/snow partitioning, but not the timing of the events. These changes in the multivariate chronology of meteorological events in the Alpine region have not been investigated in details until now to the best of our knowledge, although their stationarity is a requirement for the validity of the delta-change method. Furthermore, although our results do not exhibit significant changes in the interannual variability of the snow indicators, this is a result of our projections whereas it is only an assumption when applying a delta-change method. More in-depth comparisons between outputs of delta-change approaches and direct adjustments to RCM output could be carried out in the future, but are beyond the scope of this article.

4.4 Link with global temperature increase

The international framework for climate negotiations, culminating at the yearly Conferences Of Parties (COP), and basing the technical part of its decision process on IPCC assessments, shows a strong tendency to focus on global temperature changes. While for a number of reason this approach is limited and only partially represents climate change (Rogelj et al., 2015; Millar et al., 2017; James et al., 2017), its infusion in the public debate at all levels, from the international, national and even local level, makes it relevant to discuss and illustrate local impacts of global climate change. With Figure 6 and Tables 5 and 6 we provide such a link, thereby highlighting the specific sensitivity of the mountain meteorological and snow conditions to global climate conditions. Such figures allow stakeholders interested in snow and meteorological conditions at the local scale to directly infer
the consequences of climate policies in their socio-economic domain (James et al., 2017; Marty et al., 2017a). However, using only such an approach with a focus on the end of the 21st century, may lower the impact of the results and the motivation of stakeholders, if the consequences appear too distant in time. The power of the approach shown in this article, is that, not only it makes it possible to infer EOC impacts of climate change, but also provides a continuous vision of past and current climate context, and its most likely evolution according to state-of-the-art GCM/RCM pairs driven by RCPs. Furthermore, the data obtained indicate that the response of local meteorological and snow conditions is essentially the same regardless whether data from the beginning or end of the century are sampled. This indicates that the seasonal snowpack responds in a reversible way to global-scale climate change, and the near-term and mid-term responses can be used, in addition to the end of century information, to infer the relationship between local and global conditions using a larger dataset thereby providing more robust assessments of the influence of the global air temperature on local snow and meteorological data. This is all the more relevant in that none of the GCM-GCMs used for this study predict EOC warming below 1.5°C compared to pre-industrial levels, so that using less distant future time periods makes it possible to assess the response of the local snow conditions to 1.5°C and 2°C difference in a more robust way than EOC only (see Table 6) (James et al., 2017). Even for the lowest level of global warming, none of the model results predict that local snow conditions will be unaffected by climate change, the minimum level of decrease of mean winter snow depth being on the order of 25% for 1.5°C global increase since pre-industrial period.

In more details, these results highlight several discussion points. First of all, it is remarkable that the regression line of the local mean winter temperature with global temperature increase shows a slope of 1.1 °C°C−1, which represents a low additional warming of the mountain environment in contrast to previous studies (Durand et al., 2009a; Pepin et al., 2015). This result may stem in part from the fact that although elevation dependent warming is generally maximal in the fall and springtime, while our target period covers mostly wintertime. This low elevation dependent warming. Alternatively, this low enhancement factor could be due to the fact that the RCM grid points used for our analysis are at lower altitudes, from 612 to 1085 m, with a mean value across all RCMs of 880 m. Snow conditions at such altitude levels are generally limited already at present time, so that the local snow albedo feedback which drives much the elevation warming (Pepin et al., 2015) may be limited at such a low elevation. Addressing this issue in more detail is left open for future research, as it may imply that the temperature trends identified in this study are underestimated for this reason. Second, it is interesting to note that the relationship between snow conditions and global air temperature is different for winter mean snow depth and peak SWE. The latter shows a lower sensitivity (-20%°C−1) than mean snow depth (-25%°C−1), see Table 5. While this is first due to the different nature of the indicators (peak SWE value vs. mean winter snow depth value), this may also be due to the fact that rain on snow events (whose frequency is projected to increase) can positively contribute to SWE, through refreezing of the precipitation water in the snowpack, while not contributing to increasing snow depth. This shows that the difference of response of the snow-related indicators must be carefully assessed depending on the target socio-economic domain, because specific snow-related variables may provide distinct messages regarding their impact. While global temperature is well correlated to the snow indicators, the slope of the regression curve is not the same for all indicators, illustrating the usefulness of using a detailed snowpack model to predict the impact of climate variations of snow conditions, accounting for a maximum amount of processes operating at the boundaries and within the snowpack.
5 Conclusions

This study introduced a multi-component ensemble framework in order to provide future values of meteorological and snow conditions in mountainous regions, exemplified for a typical mid-altitude (1500 m) mountain range in the Northern French Alps. The multi-component ensemble framework makes it possible to account for the various sources of uncertainty and variability which affect future climate projections, and some if not most of whom are often neglected in past and still some of which are neglected in both previous and ongoing climate change impact studies. The multi-ensemble framework developed here addresses various sources of uncertainty and variability, drawing on several RCPs (RCP 2.6, RCP 4.5 and RCP8.5), feeding several GCM model runs from the CMIP5 intercomparison exercise, which themselves feed various RCP model runs from the EURO-CORDEX downscaling exercise, which are adjusted using the refined quantile mapping method ADAMONT against the meteorological reanalysis SAFRAN, making it possible to drive a multi-physical version of the energy balance multi-layer snowpack model Crocus. The primary material the method draws on is method defines a series of annual snow and meteorological indicators defined at the annual scale, representing various features that represent various aspects of the winter season (mean annual snow depth, peak Snow Water Equivalent, date of inception and melt out of the snowpack, mean air temperature, cumulated winter precipitation etc.), which are computed from daily values of the variables representing meteorological and snow conditions (here temperature, precipitation, snow depth and SWE).

Based on an analysis of various sub-ensembles of past, current and future observations and simulations, spanning the period from 1950 to 2100, and focussing on this particular yet representative geographical setting, the main conclusions of this study are that:

– Uncertainty arising from physical modeling of snow after the middle of the century can account to 20% typically of the simulation results, although the multiphysics is likely to have a much smaller impact on trends, because of the systematic nature of a large fraction of the error sources considered.

– The ADAMONT method appropriately adjusts the output of the EURO-CORDEX GCM/RCM model runs, making it possible to drive an energy balance land surface model such as Crocus based on the chronology of the driving climate model, thereby leveraging the caveats of using delta-change methods applied to past observations, which do not make it possible to take into account variations differences in seasonality or climatically-variable weather patterns (blocking, extreme precipitation events, etc.). The method can be readily applied to the next generation of climate model runs, generated using refined greenhouse gas emission scenarios and/or improved model components (Rogelj et al., 2015; Millar et al., 2017). This should make it possible to update quicker than in the past the climate change impact assessment, reducing the phase lag between the production of assessments of global, regional and local climate variations and of their impacts.

– The four GCM/RCM models within the EURO-CORDEX ensemble, which provided not only RCP4.5 and RCP8.5, but also RCP2.6 model runs, exhibit similar statistics at the interannual and multi-annual scale than the 13 full as the full 13-member ensemble, making results obtained for RCP2.6 comparable with results obtained for RCP4.5 and RCP8.5.
even though they are not based on the same number of models. This result may not generalize to any sub-ensemble of the available GCM/RCM runs of EURO-CORDEX, therefore we consider preferable to use as many as possible GCM/RCM model runs in ensemble-based assessments.

- Ensembles of climate projections generated under RCP2.6, RCP4.5 and RCP8.5 are rather similar until the middle of the 21st century, with the continuation of the ongoing reduction in mean interannual snow conditions, but maintained sustained interannual variability of snow conditions, playing even an increasing relative role along with the decrease of mean snow conditions. The interannual variability of meteorological and snow conditions generally induces a stronger spread in potential annual values than the As assessed in this study, for this location, interannual variability is larger than inter-model dispersion (spread) for a given RCP

scenario.

- The impact of the RCP becomes significant for the second half of the 21st century, with overall stable conditions under the RCP2.6 scenario, and continued degradation of snow conditions along with increased air temperature variations for RCP4.5 and 8.5, the latter leading to frequent occurrence of ephemeral if not almost potentially completely or nearly snow-free snow-conditions at the end of the century.

- Variations Changes of local meteorological and snow conditions show significant correlation with global temperature levels (using 30 year means), with respect to pre-industrial levels. For example, the mean variation of mean change in mean snow depth at 1500 m altitude in the Chartreuse mountain range is in the order of -25% for 1.5°C global temperature rise with respect to pre-industrial levels, and this value decreases very rapidly with increasing global temperature variations, the magnitude consistently increases along with global mean temperature reaching reductions of 65% for 3°C global temperature rise, and even 80% reduction beyond 4°C temperature rise of global warming.

While this work provides scientific results directly exploitable for snow and meteorological conditions at 1500 m altitude in the Chartreuse mountain range, our results do not directly allow extrapolation of the conclusions in other mountain regions in France or other elevations. Based, although it is expected that the response of neighbouring mountain ranges may be comparable at the same altitude level. These locations may be investigated in the future, based on the methodological framework introduced here, this will be tackled in subsequent exhaustive investigations, based on the entire wealth of and the data available in the SAFRAN reanalysis for the French Alps and Pyrenees (Durand et al., 2009b, a; Maris et al., 2009). The method can obviously be applied beyond French borders, provided that an adequate long-term observational dataset can be used as a basis for RCM output adjustment using the ADAMONT method (Verfaillie et al., 2017).

Beyond the geographical scope, which can be extended to address a wider diversity of territorial climate-related challenges, sector-specific further applications can now be considered. For example, the adjusted climate scenarios can be projected on sloping surfaces, making it possible to compute Crocus snowpack model runs able to tackle avalanche hazard evolution, thereby upgrading and consolidating the results of Castebrunet et al. (2014). Also, the adjusted climate scenarios could be employed to simulate snow conditions on ski slopes in French ski resorts, drawing on the method developed by François et al. (2014) to be applied using the version of Crocus accounting explicitly for snowmaking and grooming (Spandre et al., 2016b). This
method has shown significant potential to account simultaneously for the impact of natural snow precipitation and temperature conditions (driving the capability to produce snow) on the operating capabilities of alpine ski resorts over the past decades (Spandre et al., Under Review). It is now ready to be applied for future conditions, drawing on the framework developed in this study. Conversely, it is re-emphasized here that, while variations in natural snow conditions as projected in this work are likely to affect operating conditions of ski resorts, no quantitative conclusions can be made, given that snow management practices induce significant changes in operating conditions, which depend on intricated factors related to temperature and precipitation (Hanzer et al., 2014; Spandre et al., 2016b). Beyond these seasonal snow applications, the method is ready to use for hydropower potential, water resources assessments, glacier mass balance studies, ecology, natural hazards related to meteorological conditions and more generally environmental impact studies which can be based on mechanistic derivations of the impact of meteorological conditions on the socio-ecosystemic compartment under investigation.
